Dr. ROBERT JANKER, who spoke in German, gave a brief summary of the history of this subject, pointing out, as Dr. Reynolds had also done, that the idea was first conceived by the late Dr. John MacIntyre of Glasgow, as early in x-ray history as 1897, when he showed movements of bones of living animals. Dr. Janker then illustrated his own technique, carried out at the Roentgen Institute-Clinic at Bonn University. He had used, and partly modified, both the indirect method, in which a photograph of the screen image is taken, and the direct method, as in ordinary skiagrams. With the direct method only small objects had been taken, the rate of exposure being 22 frames per second. With the indirect method he had produced many films of laboratory animals, showing physiological and pathological reactions. Some of these had been taken at the normal rate, and in others the movement had been accelerated or slowed down as required, for special observation. The cinematograph apparatus he employed was of his own construction, with specially adapted lenses, and he had employed a Schering Kahlbaum screen and either Kodak supersensitive film or film coated with a Schleussner x-ray emulsion.

Dr. Janker then showed three reels, apparently on ordinary 35 mm. film, illustrating experiments on the anaesthetized rabbit and cat. The first illustrated normal respiration, followed by respiration under abnormal thoracic pressures and with unilateral and bilateral pneumothorax. He drew attention to the accommodation in size of the heart to changes of thoracic pressure. The changes following a thoracotomy were also demonstrated. Another effect illustrated was that of the inhalation of CO₂ in increasing the size of the heart. The filling-up of the bronchial tree with a contrasting medium was remarkably well shown, also the pumping action of respiration on the contents of the bronchus, and the pulsation of the bronchus caused by the pulsation of the heart. In another series an experimental embolism of the lungs in these small animals was shown, the purpose being to demonstrate to students the dangers of air embolism. Finally, a series of films illustrated the filling of the oesophagus and stomach, the passage of the opaque meal through the cardiac orifice, the dilatation of the oesophagus in front of the bolus—a characteristic pointed out in this country by Barclay—and the changes brought about in peristalsis by the injection of certain substances. The kneading movements of the caecum, the effect of pilocarpine, and the mechanism of defaecation were all clearly depicted in motion.

VOTE OF THANKS

In proposing a vote of thanks Dr. R. S. PATERSON said that, as often happened, workers on independent lines in this field had achieved success almost simultaneously. He foresaw great possibilities for the method in teaching and research, wherever critical analysis of movements of any sort—peristalsis, respiration, or pulsation—was desired. Interesting work had been done in recording the sound of muscle and heart movements, and there was no reason why sound should not be synchronized with the pictorial record, and a sound track attached to the film. Dr. K. J. FRANKLIN seconded the vote of thanks.

ONE HUNDRED AND SECOND ANNUAL MEETING
of theBritish Medical Association
BOURNEMOUTH, 1934

THE one hundred and second Annual Meeting of the British Medical Association will be held in Bournemouth this summer, under the presidency of Dr. S. Watson Smith. The Sectional Meetings for scientific and clinical work will be held on Wednesday, Thursday, and Friday, July 25th, 26th, and 27th, the morning sessions being given up to discussions and the reading of papers, and the afternoon to demonstrations. The Annual Representative Meeting for the transaction of medico-political business will begin on the previous Friday, July 20th. The full list of presidents, vice-presidents, and honorary secretaries of the sixteen Scientific Sections, together with the provisional time-table and programme, was published in the *Supplement* of March 31st. Other details of the arrangements for the Annual Meeting will appear in subsequent issues. We publish below the third of a series of descriptive and historical articles written for the occasion. The first, on Bournemouth and its attractions, appeared on January 6th (p. 22), and the second, on the hospitals and benevolent institutions, in our issue of March 3rd (p. 391).

SOME GEOLOGICAL AND ARCHAEOLOGICAL FEATURES IN THE NEIGHBOURHOOD
OF BOURNEMOUTH

During the Miocene Period, perhaps some twenty-five million years ago, the surface deposits in the South-East of England were gradually folded into a series of east and west ridges and valleys, resulting in the formation of the Thames Valley and the Hampshire Basin. The axis of the latter runs roughly from Poole Harbour along the Solent to Spithead. The so-called Solent River which drained it was bounded on the south by a continuous line of hills from Lulworth via Swanage to the Isle of Wight. The sea subsequently made a breach in this barrier, and the gap between the chalk cliffs at Old Harry near Swanage and the Needles is now some fifteen miles wide.

The process of rock-folding produced remarkable contortions in the strata, some of the beds being pushed through an angle of nearly 100 degrees. Very fine examples may be seen in the Purbeck Beds in the neighbourhood of Lulworth Cove, and on a smaller scale at Peveril Point near Swanage. At the base of the Purbeck formation occurs the well-known fossil forest, which consists of the silicified remains of tree trunks and roots. This deposit, together with the overlying Wealden formation, has yielded the fossilized bones of various prehistoric reptiles, including the *Iguanodon* and the Swanage *Goniopholis*. This creature, like other primitive air-breathers, had the nose passage opening into the back of the mouth, whereas the modern crocodile has the passage connected with the extreme under water without inconvenience. In 1932 a double track of footprints was found in the Purbeck limestone (Fig. 1). The footprints were each about 11 inches across, and appeared to belong to the *Iguanodon* or some creature closely related to it. Remains of various early species of mammals have also been found, all of very similar size.

The line of hills north of Swanage consists of chalk. The strata have been disturbed by a very remarkable thrust fault, which is well exposed in the cliff section near Ballard Point, and may be seen on a steamer trip from Bournemouth to Swanage. By way of contrast, the east-west valley, in which Swanage is situated, consists of the soft Wealden clay. The parallel hills and valleys of the Isle of Purbeck and the curious series of coves at its western extremity afford a striking illustration of the effects of alternating formations of hard and soft rocks on regional topography. It is instructive in this connexion to examine a geological map of the neighbourhood.

Passing eastward from Swanage we lose sight of the Purbeck, Wealden, and Chalk formations, which in the neighbourhood of Bournemouth lie many hundreds of feet below the surface. Bournemouth consists of a wide expanse of Eocene sand, in which are occasionally found remains of plant leaves, indicative of a subtropical climate. At a much later period, subsequent to the Miocene folding, the whole of the Bournemouth area seems to have lain in a wide estuary, and became covered with a considerable spread of gravel, which is responsible for the porous nature of the soil. The presence in these gravels of many thousands of stone implements shows that we have now

FIG. 1—Footprints of an extinct reptile found in the Middle Purbeck Beds, near Swanage (1932) (By permission of the Editor of *Discovery*.)

reached the age of Palaeolithic man. Some of the implements bear marks of striation on their surfaces, and it is supposed that this scratching was produced when the ground was frozen. Other evidence of the glacial conditions, which compelled early man to give up an open-air life and take shelter in caves, is furnished by the discovery of mammoth remains in the river gravels not many miles from Bournemouth. Evidence is slowly accumulating which points to the occupation of this area through all the succeeding periods of the Stone Age.

BRONZE AND EARLY IRON AGE RELICS

In the Early Bronze Age, which opened about 1900 B.C., this island was invaded by a race remarkable for its

pronounced brachycephalic skulls. These people are known as the "Beaker folk," on account of their practice of placing a cup or beaker in the graves of their dead. The body was usually laid on its side with the knees drawn up to the chest, and a monument was frequently erected over the site in the form of a large tumulus. The beakers are sometimes of singularly beautiful workmanship, being decorated with geometrical patterns incised on the clay before firing. Seldom are two found alike. They are comparatively rare, and as far as is known to the writer only seventeen have been recovered from the whole of Hampshire. Of these no fewer than eight come from Bournemouth (see Fig. 2). Two of the latter are unusual in being ornamented with finger-nail impressions. In the Late Bronze Age cremation was the traditional practice, the remains of the dead being buried in flat cemeteries in cinerary urns of rather crude shape. The chief centre of this culture lies in Dorset and Hampshire. Confining our attention to urn-fields with ten or more burials, we find eleven urn-fields recorded in Dorset and twelve in Hampshire. Of the latter, half belong to Bournemouth.

The remarkable concentration of Beaker and Late Bronze Age sites in Bournemouth is significant, and for the Early Iron Age which followed, distribution maps show a similar concentration, except that the area is now somewhat enlarged. The explanation lies in Bournemouth's geographical position near the mouth of the rivers Stour and Avon, which provided successive waves of newcomers from the Continent with easy access to the attractive hinterland of Cranborne Chase and Salisbury Plain. Furthermore, safe anchorage was to be found on the north side of Hengistbury Head in the sheltered waters opposite Christchurch. Indeed, during the whole period of the Early Iron Age, Hengistbury appears to have been one of the most important harbours on the south coast of Britain, only losing its importance with the coming of the Romans in the first century A.D., when the development of London caused the main route of Continental traffic to shift eastwards up the channel.

Evidence has recently been produced that the Dorset and Hampshire coast, between Weymouth and Southampton, was subjected to an invasion of Iron Age folk about 50 B.C. The invaders were the Belgae, who came from Northern Gaul, and shortly afterwards spread out over the whole of Wessex, making their headquarters at Silchester under a king named Commius. His kingdom was not destined to survive very long, giving way, after a stubborn fight, to the power of Rome. Remains of Belgic settlements have been identified at five different sites in Bournemouth, and at seven others in the adjoining neighbourhood. The series of hill forts situated in the Stour Valley between Dudsbury and Hambledon Hill probably belongs, in its origin, to the Early Iron Age. Such spots would have been used as places of refuge in local tribal warfare. In the Romano-British period there was a considerable peasant population, spread through villages in and around Cranborne Chase, and it was probably to protect this civilization from Saxon invaders from the north-east, that Bokerly Dyke and Combs Ditch were thrown up in the fourth and fifth centuries of our era.

OTHER LOCAL RELICS OF INTEREST

Further details of certain local discoveries are here added partly because of their intrinsic interest and partly because they throw light on the problems and methods of archaeological research. A Neolithic long barrow, now very nearly ploughed out, has recently been identified near Hadden's Hill by the aid of aerial photography. In the Pokesdown urn-field, a Late Bronze Age burial was found to cut into a previous burial of Middle Bronze Age date, the later urn resting on the broken fragments of the earlier one. At Kinson an interesting example of overlap of cultures was recently discovered, Late Bronze Age and Early Iron Age burial urns being found side by side. The three sites last mentioned are all situated within the county borough boundary.

Two remarkable instances may be given which illustrate the richness of certain local sites in archaeological remains. A Roman well (circa A.D. 100), excavated by the writer last year in a quarry near Swanage, was found to have been dug through an Early Iron Age habitation site, some five hundred years older, while a few yards away an Early Iron Age pit had disturbed a Middle Bronze Age interment containing a food vessel, flint knife, and human skull; the rest of the body was probably destroyed in making the later excavation. The other example is that of a gravel pit near Wimborne, which has yielded Palaeolithic and Neolithic implements, a Late Bronze Age urn, large quantities of Belgic pottery, as well as two storage pits containing grain of the same period, and a Romano-British kiln, with remains of upwards of two hundred vessels.

The preservation of antiquities necessarily depends to a considerable extent on the nature of the soil. Early Iron Age sites in Bournemouth generally yield little beyond pottery fragments, but when sites of the same age are examined in the limestone district around Swanage the record is found to be much more complete. Bones of the sheep, horse, and ox are commonly met with, as well as limpets and other shells, revealing something of the diet of these early days. Bone needles and combs have also been found (see Fig. 3). Such discoveries do not indicate that Bournemouth was formerly less civilized than her neighbours in the Isle of Purbeck, but merely that all the bone objects on the Bournemouth sites have long ago perished, owing to the porous nature of the soil. While a subsoil of sand or gravel may be an excellent asset for publicity purposes, the archaeologist secretly prefers limestone!

J. BERNARD CALKIN, M.A. CANTAB.

The Board of Education has reissued in pamphlet form a revised list (No. 42) of certified special schools for blind, deaf, defective, and epileptic children in England and Wales, and also institutions recognized by the Board as providing higher education for such children, together with a list of nursery schools. The institutions are grouped according to type and arranged in counties, details being given of the available accommodation in each. Copies of the list may be obtained from H.M. Stationery Office or through any bookseller (price 9d., postage extra).

FIG. 2.—Early Bronze Age beakers found in Bournemouth. Date circa 1750-1600 B.C. Left to right: 1 to 3, Sheepwash, Iford (1933); 4, Kinson (1929); 5, Boscombe Cemetery (1921).

FIG. 3.—Iron Age objects found near Swanage, Dorset. 1 and 2, bone comb handles; 3, spindle-whorl of earthenware; 4, shale bracelet (Romano-British); 5 and 6, bone needles.

JOINT TUBERCULOSIS COUNCIL

SOME RECENT PUBLICATIONS

The report of the Joint Tuberculosis Council for the year 1932-3 contains a reference to the important memorandum on improvement of the Tuberculosis Service, which has received mention previously in these columns. It envisaged better training for medical students and the wider utilization of the clinical material available at dispensaries and sanatoria. Emphasis is again attached to the need for taking all possible steps to secure the active co-operation of general practitioners in the prevention and treatment of tuberculosis. Topics singled out for special consideration include the utilization of residential institutions for tuberculosis; the nature of the tuberculin reaction; and the diagnosis, treatment, and prevention of thoracic tuberculosis in children.

REPORT ON RESIDENTIAL INSTITUTIONS

In May, 1931, the Joint Tuberculosis Council appointed a committee to report on the best utilization of residential tuberculosis institutions, and the resulting memorandum has now been issued. With the inauguration of sanatorium benefit under the National Insurance Act, and the consequent demand for increased institutional accommodation, an unfortunate idea became generally prevalent that the necessary period for sanatorium treatment was only about three months. This affected the provision of special facilities for the serious treatment of the disease, with the consequence that some institutions have become to-day convalescent homes rather than sanatoria. Small pavilions in fever hospitals are still being used for the reception of tuberculous patients who really need active treatment under expert direction. The council believes that at the present time the most important needs of many tuberculosis institutions are efficient x-ray plants and facilities for collapse therapy. Where facilities for major surgery cannot reasonably be provided, it is added, arrangements should be made whereby this can be undertaken at another institution. To this primary recommendation is joined the warning that institutional beds should be used for their intended purpose; greater attention ought therefore to be paid to diagnosis and intensive clinical and pathological investigation. A properly equipped treatment institution should deal with patients in all stages of the disease where definite improvement may be anticipated. It is insisted that to submit a patient with a cavity to sanatorium regime limited to rest, food, and fresh air for a period of from three to six months, and to hope for arrest, is to hope for the improbable. In some cases surgical measures taken without delay may be successful. It is regretted by the committee, therefore, that many cases are still being relegated to institutions where no active treatment on modern lines is being conducted. Special accommodation may have to be found for advanced pyrexial cases which are steadily going downhill. Some of these patients may be accommodated in the "sanatorium-hospital"; others in the public assistance hospital, which should possess adequate facilities for dealing with tuberculosis; and others at home if the conditions are suitable. Some patients will require maintenance in residential institutions owing to poverty. Those who are steadily improving, or are capable of responding to active medical or surgical treatment, should be treated in tuberculosis institutions belonging to the public health authority, or at its expense elsewhere. Progressively deteriorating cases will at present come into the hands of the public assistance authority, as also will those patients who are mentally defective and intractable, while the disposal of stationary cases should be a matter for the joint consideration of public health and public assistance committees. In any scheme, it is recommended, the dispensary and institutional sides should be operated in the closest liaison. The criterion for treatment in approved institutions should be clinical rather than economic. Major operations should be performed by surgeons with special experience of this work, and attached for this purpose to the staff of the institu-

tion. Special attention should be given to young adults suffering from pulmonary tuberculosis, and residential treatment for them be arranged as quickly as possible. For the ambulant, apyrexial, sputum-positive cases—essentially an economic and public health problem—some extension of village settlement principles might be envisaged. In an appendix to this report Drs. G. Lissant Cox and D. A. Powell discuss the erection and equipment of such tuberculosis institutions on the basis of their experience in Lancashire and Wales. Copies of the report may be had from the honorary secretary, Dr. Ernest Ward, 123, Torquay Road, Paignton, price 6d., post free.

THE TUBERCULIN REACTION

Dr. W. H. Tytler, of the Central Tuberculosis Laboratory of the Welsh National School of Medicine, reviews the bearing of laboratory data on the tuberculin reaction in a pamphlet published by the council. The work of recent years has shown definitely that the active principle of tuberculin responsible for eliciting the characteristic skin reaction is contained in the normal protein fraction of the tubercle bacillus. The most readily prepared and most active protein is one which is soluble in water at neutral reaction, and may be extracted from the bacillary bodies in amounts up to at least 10 per cent. of the original dry weight. It is combined with relatively large amounts of nucleic acid, which may be split off by appropriate means, and its activity is strikingly constant. Protein recovered from tuberculins derived from the growth of tubercle bacilli in liquid media usually shows some evidence of denaturing; it has a much lower nucleic acid content, and usually a lower solubility than the extract preparations, while its tuberculin activity is usually less, though still high. These purified tuberculo-protein preparations give skin reactions which are as a rule rather more clean-cut than those produced by old tuberculin, and show less surrounding erythema. They can be stored indefinitely in the dry form without loss of activity or solubility; they are assessable on a dry weight basis, and can be made up in permanent glycerin solution at a strength at least ten times that of standard tuberculin. Their use has spread rapidly in America, and Dr. Tytler believes that they will supplant old tuberculin for diagnostic skin testing. He calls attention to the variability of standardization of tuberculin, the hitherto universally used lethal reaction method now giving place gradually to the intradermal method, which is probably more sensitive, cheaper, and gives values relevant to the method employed in the great bulk of diagnostic tuberculin testing. While the danger of any error arising from artificial sensitization in the non-tuberculous subject seems to be remote with any type of tuberculin, Dr. Tytler points out that there is considerable evidence that in the tuberculous subject the application of tuberculin may produce a temporary increase in general sensitivity, or more particularly in local sensitivity at the site of application. He concludes that, where quantitative values are sought from the intradermal method, by progressive increase of the tuberculin concentration, it is probably important that no injection shall be made at the immediate site of a previous test.

THORACIC TUBERCULOSIS IN CHILDREN

The Joint Tuberculosis Council also issued this year the report of a special committee on the diagnosis, treatment, and prevention of thoracic tuberculosis in children. It is strongly urged that a positive diagnosis and notification should be avoided unless there is definite clinically active disease. In the first two years of life positive tuberculin skin reactions are significant, but not later. Positive x-ray findings are of prime importance, but "large root shadows" with inner zone striation are common in healthy town children, especially in those who have had measles; such shadows are not in themselves evidence of tuberculosis. Tracheo-bronchial glands are clearly seen in antero-posterior films only when they are large, calcified, or laterally situated, especially on the right side. A lateral film is essential to confirm their presence in many cases. Such glandular enlargement may

be associated with clouding of the adjacent parenchyma. Apical shadows suggest tuberculosis if recent pneumonia can be excluded, as also do woolly shadows if well out in the lung fields. Of the forms of blood examination the red cell sedimentation test, the Arneith index or its modifications, and the lymphocyte-monocyte ratio may all give early indications of activity even in cases which still maintain a normal temperature and a satisfactory body weight. Gastric lavage and the examination of the faeces may be helpful in many cases, and pharyngeal swabs taken during fits of coughing sometimes yield positive results.

ROCKEFELLER MEDICAL FELLOWSHIPS

The Rockefeller medical fellowships for the academic year 1934-5 will shortly be awarded by the Medical Research Council, and applications should be lodged with the Council not later than June 1st. These fellowships are provided from a fund with which the Medical Research Council has been entrusted by the Rockefeller Foundation. Fellowships are awarded by the Council, in accordance with the desire of the Foundation, to graduates who have had some training in research work in the primary sciences of medicine, or in clinical medicine, or surgery, and are likely to profit by a period of work at a university or other chosen centre in the United States, before taking up positions for higher teaching or research in the British Isles. In special circumstances the fellowships may be tenable at centres of research not in America.

A fellowship held in America will have the value of not less than £350 a year for a single Fellow, with extra allowance for a married Fellow, payable monthly in advance. Travelling expenses and some other allowances will be paid in addition. Full particulars and forms of application are obtainable from the Secretary, Medical Research Council, 38, Old Queen Street, Westminster, S.W.1.

England and Wales

London Mental Hospital Provision

The total number of persons of unsound mind under the Lunacy Acts for whom the London County Council was responsible on January 1st last, and of voluntary and temporary patients received under the Mental Treatment Act at the county mental hospitals on the same date, was 25,852 (11,185 males and 14,667 females), an increase of 119 on the year. This excludes the figures for Maudsley Hospital, where 230 patients, all of them voluntary, were being accommodated; in addition, the Council provides accommodation at Tooting Bec Hospital for 1,008 aged patients of unsound mind without formal reception orders. On the same date the number of London patients detained under the Mental Deficiency Acts in certified institutions provided by the Council was 5,319. The financial estimates for the Council for 1934-5 include £45,000 and £34,285 for the erection of the first sections of Ewell Mental Hospital and Maudsley Hospital respectively, £56,710 for the provision of additional accommodation for nurses, new admission villas, and works at various mental hospitals, and £71,710 for works at certain institutions for the mentally defective.

A New Mental Hospital in Essex

The local authorities of East Ham and Southend, though separated almost by the breadth of a county, are co-operating in the establishment of a new institution for their mental patients, to be known as the East Ham and Southend Mental Hospital. An area of 500 acres has been secured at Runwell, near Wickford, in Essex, in one of the pleasantest parts of that county, and here it is intended to erect an institution accommodating at first 875 beds, and ultimately, when further blocks have been built, a

total of 1,015. Between forty and fifty separate buildings will be put up, comprising administration, admission, and "closed" units, nurses' home, infirmary, convalescent home, chapel, and recreation hall. The estate will have its own power-house, electric plant, water storage tanks, laundry, farm, large vegetable gardens, and playing fields. A feature of the construction, and one which has marked recent mental hospitals, will be an absence as far as possible of signs of restraint; the buildings will be light and airy, and sanatorium-like, and much use will be made of verandas for sun treatment. The new hospital has been designed to afford opportunity for the earliest expression of some of the new regulations which the Board of Control has under review concerning the planning and construction of such institutions, and there has been considerable conference with officials of the Board, whose chairman, Mr. L. G. Brock, will lay the foundation stone on June 20th. The architects are Messrs. Elcock and Sutcliffe, who designed the new "Bethlem" in its country surroundings, and the work is expected to take from eighteen months to two years.

London Ambulance Service

The London Ambulance Service now comprises in its accident section sixteen stations with eighteen motor ambulances in commission and seven reserves. The total number of calls received during the calendar year 1933 was 42,384, involving 44,250 cases, an increase of 1,746 on last year's calls, but below the highest recorded total, which was 44,178 in the year ended March 31st, 1930. Of the total cases involved, street accidents numbered 17,789, or 40.2 per cent. The other principal causes were: accidents other than street accidents, 4,852 (11 per cent.); sudden illness, 9,926 (22.4 per cent.); and parturition cases, 4,416 (10 per cent.). The total mileage amounted to 190,965. The average time occupied in reaching casts was 6.3 minutes, and the average time between the receipt of call and arrival at hospital was 14.4 minutes.

Scotland

Co-ordination of Public Health Services

At a meeting of the Public Health Committee of Edinburgh Town Council, on April 24th, it was stated that at the present time the departments of the medical officer of health, the chief veterinary inspector, and the chief sanitary inspector had each, as a general rule, no cognizance of what was going on in the other two departments. It was agreed by the heads of these departments that this was an undesirable state of affairs, and that the medical officer of health should be provided with full information on matters arising in connexion with the other two departments. It was also arranged that if the medical officer of health, on information given to him, decided that action was necessary for the public welfare, the other departments would take precautions along the lines which he indicated. In regard to staffing, it was agreed that while a complete fusion of staffs would not be practicable, changes in this direction should be made whenever opportunity offered. This would achieve as large a measure of co-ordination as was possible in the present circumstances. At the same meeting the question was discussed of the best type of building to be erected for the rehousing of persons dispossessed through slum clearance operations. In a new area, laid out on the margin of the city at Niddrie Mains, there would be about 1,930 houses spaced at twelve to the acre; the disadvantage of this scheme, from the workers' point of view, was that the furthest house would be an additional

three-quarters of a mile from the centre of the city. The problem of rebuilding on cleared areas in the centre of the city was still more acute; many workers had to begin work in the morning before transport was available, and they had, therefore, to live close to their place of occupation. For this reason four-storied houses had been built on most of the areas already demolished. In some parts of the country the balcony type of house had allowed as many as twenty-five houses to be built with one staircase. There were certain disadvantages to this type, however: light was cut off from the windows and there was a lack of privacy. The common access balcony, as used by the London County Council, was hardly ever found in modern Continental houses; in several large cities, such as Vienna, it was shown by pre-war experience to be disadvantageous. It thus appeared that for Edinburgh the conditions now adopted in central London were unsuitable, and that houses should be limited to four stories, and should be built with a central staircase. The question of nursery schools was also considered, and it was recommended that their development under voluntary bodies should be encouraged, and that grants should be increased where necessary.

Mental Health Lectures

The two Dr. James Watson lectures were delivered in the Hall of the Royal Faculty of Physicians and Surgeons, Glasgow, on April 26th and 27th, by Dr. Hamilton C. Marr, Commissioner of the General Board of Control for Scotland. In his first lecture, on "Madness in Literature and Life," Dr. Marr cited classical cases of insanity described in literature, and referred to the madness of Dido and the *Orlando Furioso* of Ariosto, and the vein of madness running through George Borrow's *Lavengro*. An abnormal power of sensation existed in some individuals, who could tell when cats, spiders, mice, and other animals, to which they had a peculiar aversion, were in the neighbourhood. These susceptibilities were akin to the hypersensitiveness of individuals in whom certain plants produced an erythematous rash. All these idiosyncrasies were abnormal when they engendered fear and led to impulsive action. Into this category fell many phobias of mentally unstable persons, such as fear of closed or open spaces, or of darkness, and phobias leading to impulsive action were exhibited in their gravest forms by homicidal and suicidal insanities. In his second lecture, in which he considered the causes of dreams, Dr. Marr said there was a widespread belief that dreams took place in normal sleep, but there was no evidence to support that view. Dreams might be dimly impressed on consciousness, but when they were suddenly impressed, as in a nightmare, they interrupted sleep, and might induce morbid fear. In many cases of shell-shock disturbing dreams had been a cause of insomnia and melancholia. Such dreams usually occurred between waking and profound sleep, and if the dreamer were watched his condition exhibited deep agitation and restlessness, and he frequently talked. Dreams bore the same relation to sleep as confusional mental states did to normal mental action, and he believed that both were almost invariably excited by toxic conditions of the blood. In both, dissociation was marked and orientation was disordered. Perceptions and ideas might be formed and grouped without reference to place or time in the dreamer's conscious life, and these could not be turned into a logical or coherent whole. The individual might know that he had been dreaming, and when dreams obtruded on the conscious personality they might be remembered with a feeling of depression or even of fear, which might sometimes induce suicidal impulse; but in general these effects were counterbalanced by the mental relief of realizing that the dream was unreal.

Reports of Societies

THE VALUE OF THE TREATMENT OF MENTAL DEFICIENCY

The Sections of Epidemiology and Psychiatry of the Royal Society of Medicine held a combined meeting on April 27th for a discussion on "The Value of the Treatment of Mental Deficiency." Dr. J. D. ROLLESTON was in the chair.

Dr. F. C. SHRUBSALL said that "mental deficiency" was a legal or social term rather than, strictly speaking, a medical one. The earlier enactments for the care of mental defectives were directed to the protection of their property, and only in the last century had there come any idea of the social rehabilitation of individual defectives. Mental deficiency was defined in the Act of 1927 as a condition of arrested or incomplete development of mind existing before the age of 18, whether arising from inherent causes or induced by disease or injury. This definition regularized the admission to institutions of those suffering from the after-effects of sleepy sickness; it also opened the doors to some young sufferers from organic psychoses. Of 10,000 mentally deficient individuals in London, 29 per cent. were found to belong to the category of secondary amentia, but it was generally estimated that the proportion of secondary to primary amentia among persons who remained in the community was much lower, the secondary aments being often of lower grade and so more likely to be dealt with by local authorities. Dr. Lewis, for the Wood Committee, found the proportion of grades as follows: idiots 4.1 per cent., imbeciles 17.7 per cent., feeble-minded 78.3 per cent. In the first 10,000 cases dealt with in London the proportions were respectively 5.3, 35.7, and 59 per cent. The Wood Committee also estimated that in the population at large about 8 in every 1,000 were mental defectives, which in London would mean about 35,000 defectives, but on another computation would only be 25,000. Those ascertained in London were: 11,000 under institutional care, 4,000 under guardianship or supervision, and 4,500 in special schools; the names of over 11,000 special school leavers not under supervision were also known, so that the ascertained figure was about 31,000, or midway between the two estimates. The average weekly cost in institutions for mental defectives ranged from 26s. for the training of the higher-grade defectives to 35s. 6d. for children. It was sometimes said that mental defectives were prospective criminals, but in fact the after-careers of those leaving London special schools showed very definitely the stabilizing effects of education. In two recent years 168 mental defective adults were brought to notice through police court action, and of these sixty-five had attended special schools—a very small proportion indeed of the special school leavers. Dr. Shruballs also gave some interesting figures relative to defective parents and their children.

Defective Parent	Number	Average Intelligence Quotient	Number of Children Examined	Average Intelligence Quotient
Father	36	63.0	62	87.2
Married mother ..	83	61.0	113	85.5
Unmarried mother ..	150	59.5	169	78.8

He pointed out that the average intelligence quotient of the children was considerably above that of the defective parents. As to actual medical or surgical treatment there was little to be said. A few cretins were benefited by thyroid treatment, but their number in any event was small, and by the time the case came to the attention of the education authority the opportunity for effective glandular treatment with the hope of preventing mental arrest had passed away.

Dr. W. REES THOMAS asked what was to be the aim of those who dealt with mental deficiency, assuming that it could not be eradicated. He defined such aim as the endeavour to instil a measure of ability to adapt to modern social conditions. Methods of social treatment included voluntary and statutory supervision, guardianship, institutional care, home training, and occupational and industrial centres and schools. The success of the training methods in an institution might be judged from the fact that a large number of defectives returned from institutions to resume ordinary family and community life. The defectives who were retained in institutions were those who must be there because they needed training and supervision unobtainable for them elsewhere, or because they were a danger to society. It did not follow that the great majority of high-grade defectives required permanent segregation, but they did need such training and control during childhood as to bring out the best in them. One of the most important functions of the institution was to train the patient to make him wholly or partly self-supporting, thereby giving him a better chance to make normal adjustments. Occupation formed an essential part of the life of the defective inside a colony, and if he could be made partially self-supporting it brought happiness to himself and some measure of financial relief to his friends. When guardianship had been a failure it was because the patient was unfit for this mode of treatment, or because of some unhappy selection of the guardian. Under statutory supervision many patients were able to remain at home, and, on a reduced scale, to live happy and useful lives. By voluntary supervision was meant the visiting of defectives in their homes, such visits often proving extremely helpful both to the parents and to the patient. There were 154 occupation centres in this country, and twenty-two industrial centres. At the beginning of this year the number of defectives reported to mental deficiency authorities was 105,500, or 2.65 per 1,000 of the population. The expected proportion, according to Dr. Lewis, was 4.25, so that apparently only rather more than half of the defectives were known to the authorities at the present moment. It was considered that approximately 2 per 1,000 of the population would be defectives requiring institutional treatment, and that proportion had actually been reached in one or two areas. This would make it probable that institutional treatment for about 80,000 would be required. He believed that in present circumstances the methods of dealing with the defective should be regarded as a compliment to British good sense and medical instinct.

Dr. NOEL BURKE said that in discussions of this kind there was an unfortunate tendency to generalization and simplification, which was not justifiable. The point should be emphasized that mental deficiency was not a disease entity, but a symptom or state occurring in several different forms and in many entirely different conditions. It was necessary to consider not only degrees of deficiency, but all sorts of distinct conditions revealing different qualities and temperaments. Within each group of defectives there was considerable diversity in the pattern of the deficiency, and the title of the discussion should have been not "The Treatment of Mental Deficiency," but "The Treatment of Patients with Mental Deficiency." Many patients of the medium and higher grades suffered from the feelings of the outcast and inferior when exposed to the competition of the normal world. The provision of a modified or specialized environment built to suit the defective saved him from this situation, and to that extent made him happy. It was not uncommon for parents, with every good intention but with unconscious cruelty, to apply to the defective child a continual drive and pressure in the effort to procure normal standards of attainment which could not possibly be reached. Some defectives suffered from specialized physical handicaps as well as a lack of intelligence, yet even these people, as the speaker showed by exhibiting some specimens of their work (needlework, basket-work, and the like), could overcome their handicaps in a remarkable manner. He emphasized the value to the patient of restoring his usefulness to the community.

There were instances where wrong treatment had been applied, and the results were detrimental to the individual. He had seen several young adults only slightly defective on intellectual standards who, because of behaviour problems in their boyhood, had been certified and sent to institutions for defectives. In the present day such cases could, and probably would, be given the benefit of the child guidance clinics. He had also found a definitely adverse effect on many defectives if they were subjected to treatment in the environment of a mental hospital instead of in that of a mental deficiency institution.

Dr. RALPH WILLIAMS mentioned that mental defectives were often happier at monotonous work than persons of normal intelligence. At a special school in Bermondsey, adjacent to a packing factory, the defectives were taught packing, and those who afterwards entered the factory succeeded at the job against the competition of normal girls. As a medical officer at Broadmoor many years ago he was brought into contact with a number of feeble-minded persons who had committed serious crime, and under the regime of the asylum they were quite satisfactory and well-behaved individuals. In his view the happiness produced and the crime prevented by institutional care were well worth the expenditure and trouble.

Dr. LETITIA FAIRFIELD commented upon the relative unpopularity of this subject as compared with the sterilization of the defective or any aspect of the sex problem. It was not fashionable to think of defectives as fellow human beings, towards whom the community had an obligation. Many false deductions had been drawn as to the criminal character of the defective, yet the activities of the criminal defectives in London would only make one busy morning's work at one police court in the year. The casual wards of London had been combed out by expert officers, but last year only two defectives were discovered. She reminded the meeting that the problem of training the defective was a permanent one. However drastically they might attempt to deal with their fellow citizens by sterilization or other means, there would always be a lower 10 per cent., unless, of course, human beings began to breed completely to type. There would always be certain individuals who tended to be exploited by their more intelligent fellows, and the problem of training and adjusting the less intelligent was a permanent one, not to be shirked on account of any "pseudo-scientific smatterings of applied biology."

Dr. G. R. A. RUDOLF spoke of the work at Brentry colony, where during the past few years some radical changes had been made in administration, giving certain of the defectives increasing privileges in parole and the management of their own quarters. The behaviour records showed a marked improvement under this regime. The number of attempted escapes was a rough index of the state of discontent, and this number had also notably diminished since the new system had been instituted.

Dr. ISABEL WILSON said that one often heard the criticism that money spent on defectives was wasted, but the case, not only of the defective child but of the hard-pressed home from which he came, had to be remembered. Those who had seen the stress of mothers with defective children would not agree that this was wasted expenditure. It was also said that the institutions did not teach the children anything. This again was not true, except, perhaps, that not enough was taught the defective about the common facts of life.

Dr. MURDO MACKENZIE commented upon the optimistic picture presented by those concerned with mental deficiency as compared with the darker one which psychiatry in general must exhibit. Despite Dr. Burke's objection to generalizations he would frame one—namely, that neurologists saw patients who were moderately affluent, and called their condition a neurosis; psychoanalysts saw patients when they had lost some money, and called their condition a psychoneurosis; while psychiatrists saw patients in whom the precipitating factor of the illness was financial distress, and their condition was described as a psychosis. Dr. Burke had also objected to simplification, but while this might be undesirable in mental deficiency

it was the one thing wanted in psychiatry. There were now in psychiatry so many clever people that the subject was becoming too complex for any ordinary person to understand.

Dr. W. A. Potts corroborated Dr. Rudolf's observations as to the response which might be obtained from the proper treatment of mental defectives. It had to be remembered that the mental defective was a different type from the psychotic. The latter was suffering from a condition which affected his whole mentality, whereas a certain number of defectives had exceptional ability in particular directions. Dr. Potts also mentioned the influence of environment. A Birmingham observation had shown that feeble-mindedness corresponded fairly closely in incidence with the slum character of the area and the death rate, but idiots were in the same proportion in the better areas as in the worse.

Dr. C. J. C. EARLE, as one who had care of a hostel for high-grade boys, spoke of some of the advantages and disadvantages of institutional treatment. When boys left the institution they were quite unused to freedom, and tended to behave foolishly at first, but under a system of semi-complete freedom they showed very marked improvement. Sir WELDON DALRYMPLE-CHAMPNEYS, who as one of the honorary secretaries had suggested the discussion, remarked on its encouraging character, and its indication that real progress had been made in this field of mental deficiency, but it was a progress which would have been unthinkable in any other than a Christian civilization.

Dr. SHRUBSALL, in reply, said that treatment should not be judged from the curative standpoint, but envisaged as the socialization of the mental defective. The real emphasis should be laid on the home and on the individual. In an institution there could be little chance for moral choice, but there was something to be said for allowing the inmates of an institution to have a measure of moral option so that they might be better immunized against the temptations of the outside world on discharge. Dr. REES THOMAS commented on the large number—from 10 to 15 per cent.—of mental defectives who were certified under the Lunacy Acts; many of them had received training as mental defectives. Dr. NOEL BURKE repeated the remark of the Jesuit: "Give me the child before he is 7, and you can do what you like with him afterwards." He looked forward to the time when defectives would be ascertained before they reached the age that brought them within the purview of the education authority, and before they became ruined by contact with the less favourable aspects of the world against which, from their own resources, they could find no suitable defence.

BREECH PRESENTATION.

At a meeting of the North of England Obstetrical and Gynaecological Society, held at Liverpool on April 6th, with the president, Professor DANIEL DOUGAL, in the chair, Dr. J. W. BURNS and Mr. MARSHALL (Liverpool) read a paper entitled "Breech, its Aetiology, Diagnosis, Prognosis, and Treatment, with Special Reference to the Treatment of the After-coming Head."

Dr. Burns contended that much of the present-day teaching on breech presentations in the textbooks was old-fashioned, unquestioned by recent writers, and in many instances unsupported by facts. As a result there was a foetal mortality of 15 to 30 per cent. in breech cases throughout the country. The bulkiness of the full breech was the main cause of vertex presentation, and any factor which disturbed the normal relation between the size of the full breech and the cephalic pole of the foetus encouraged breech presentation. Anything, too, which altered the shape of the interior of the uterus also predisposed to breech presentation. Difficulties in diagnosing these cases, especially the frank breech, were described. The great risks of breech labour, for both mother and child, were emphasized. Dr. Burns maintained that there was considerable risk of separating the placenta by the manipulations of the uterus which were necessary in carrying

out the operation of external version. It should not be carried out as a routine, nor attempted before all the aetiological factors had been considered. In the management of labour everything possible must be done to prevent early rupture of the membranes. The patient was put to bed as soon as labour started. She was encouraged not to bear down during the pains. The usual enema or purgative was not given, as being likely to cause expulsive efforts. One vaginal examination was made to find out whether the cord was presenting. A comfortable binder ("labour belt") was applied, devised by Sister Miller of the Liverpool Maternity Hospital; it had numerous buckles and straps, which could be readjusted from time to time. There was much to be said for inserting a sausage-shaped balloon filled with water into the vagina to support the forewaters until the os was fully dilated. It was very much like that suggested by Farquhar Murray for the treatment of placenta praevia. During the first stage the patient was given nourishing drinks. She was encouraged to rest between pains. Bromides and chloral were useful, particularly the latter. When the membranes ruptured a vaginal examination was made to find out whether the cord was prolapsed, how much dilated the cervix was, and whether the legs were extended, if this had not been discovered in the ante-natal period. Nothing more was done until the breech appeared at the vulva, except that the labour belt was adjusted periodically from above down as the uterus descended. When the breech appeared the patient was placed in the cross-bed position, and a Clover crutch applied; the binder was tightened. No handling of the fundus was allowed, because of the danger of causing premature separation of the placenta. The attendant felt for the feet as soon as the buttocks were born, and gently lifted them over the perineum; he took care not to pull on the limbs. The umbilicus usually followed with the next pain. The cord was found and drawn down, so that further descent of the infant might not cause tension on it, and either damage the umbilicus or pull on the placenta. Dr. Burns thought it high time that teachers refrained from instructing pupils to endeavour to place the cord in some position where it would not be subjected to pressure. This was an impossibility, and no one nowadays attempted it. After the next pain a finger was inserted to find out whether the arms were in the pelvis; if so, they were gently drawn down. The shoulders followed with the next pain. At this stage the head was entering the brim. The attendant supported the body, and allowed internal rotation of the head to occur; as soon as the occiput had come forward he allowed the body to hang from the vulva. This brought about flexion of the head, and brought the nape of the neck well into the subpubic angle, as follows. The mother's perineum and soft tissues acted as the fulcrum. The suboccipital area of the infant's skull was in contact either with the back of the symphysis or the descending rami of the pubes. The child's weight, acting through the neck and across the fulcrum, forced the head to rotate on its horizontal axis—that is, flexion was induced. This method of producing flexion acted whether the head was just above the brim or whether it had entered the pelvic cavity. If the head was at the brim this method had several advantages: no traction was required by the operator; the shortest diameters of the child's head were rolled through the brim (that is, the suboccipito-frontal and suboccipito-bregmatic); there was a minimum of force necessary to produce flexion of the head (that is, the child's body weight was used); undue haste in delivery was avoided; there was no need for fundal or suprapubic pressure, and so the danger of premature separation of the placenta was minimized. If the head was in the cavity flexion of the head was still necessary, so that the shortest diameters of the child's head might distend the perineum, and thus the risk of tearing it or damaging the child's head might be minimized. By allowing the baby to hang from the vulva for one or two minutes the nape of the neck was brought more into the subpubic angle without the use of undue force. The force employed was limited by the child's body weight. As soon as the suboccipital area of the head could be seen in the subpubic angle delivery could be brought about by lifting the child up

towards the mother's abdomen. The operator should stand on the right side of the patient, and, taking the child's feet in his right hand, exert tension on the body from the moment the feet were seized. This tension must be enough to keep the neck of the child taut, and it was maintained while the legs and body were lifted in an arc until the body was vertical. By this manoeuvre the suboccipital area was made to rotate around the point of contact between the skull and the pubic rami, so that the suboccipito-mental diameter distended the perineum, then the suboccipito-frontal, and lastly the suboccipito-bregmatic. If tension was not maintained throughout this manoeuvre the child's head simply rotated within the pelvis. The occiput receded and the perineum was not distended. Further, the child's neck was merely bent, and much damage might be done to the structures in it without the head being delivered.

Mr. Marshall described the technique he used in delivering the frank breech in primigravidae. As soon as the anterior buttock was showing the mother was put in the lithotomy position, the whole perineum infiltrated with about 50 c.cm. of 1/2 per cent. novocain solution, the index finger placed in the anterior groin, and descent with the pains aided by traction. When the anterior buttock was showing well, and the posterior strongly bulging the perineum, a medio-lateral episiotomy was performed. The posterior groin was then reached, if necessary, and the buttocks were born. Chloroform was administered on an open mask, and the extraction completed. When the arms had been brought down the body was allowed to hang from the vulva for some moments. In under half the cases the amount of neck visible lengthened, and the head entered the pelvic cavity. The head was then delivered by Dr. Burns's method. If the head did not enter readily, or there was delay in its descent through the passage, pressure with the free hand was applied to the head just above the pubes. In most cases delivery was easily effected by these methods. In a few of the very early cases forceps were used, but now this was very seldom necessary. Results of thirty-three consecutive breech deliveries in primigravidae were shown. One infant (3.03 per cent.) was stillborn: this was one of the early cases, and was one of twenty-seven in which the legs were extended. The head was difficult to extract, and Mauriceau's grip was used to bring it through the outlet. The average weight of the babies was 7 lb. The value of the perineal anaesthesia was stressed: the mother bore down with less pain and apprehension, groin traction could be done almost painlessly, and episiotomy could be done at any time without resorting to general anaesthesia. To patience and the above methods Mr. Marshall attributed the small number of cases in which it had been necessary to decompose the extended breech and extract. This was done in only two cases: groin traction had failed in one, and in the other unsuccessful attempts had been made to deliver before admission. The technique was illustrated by a film, in which the delivery of four recent cases was shown. In the summing up it was emphasized that no midwife should be allowed to undertake a breech labour unassisted: she should send the patient to her own family doctor or to an institution as soon as the diagnosis had been made.

Fluid Restriction in Hypertensive Albuminurics

Mr. W. J. CHISNALL (Liverpool) read a paper on "Fluid Restriction in those Albuminurics of Pregnancy associated with Hypertension."

His paper was based on records of thirty-nine cases of pre-eclampsia, defined as a disorder of pregnancy associated with albuminuria, oedema, and hypertension without evidence of previous nephritis. They were treated at the Walton Hospital between October, 1932, and October, 1933. The treatment advocated was described by Arnold and Fay in *Surgery, Gynecology and Obstetrics* of August, 1932. He said that there was a disturbance of fluid metabolism in pre-eclampsia, resulting in a storage of fluids. This was not the cause of the con-

dition, but one of many effects due to an unknown cause. The treatment advocated had as its object the correction of the disordered fluid metabolism. There occurred in the disease a progressive diminution in urinary output: in eclampsia itself as little as 100 c.cm. might be passed in twenty-four hours, although there was no diminished intake before the onset of severe symptoms. This diminution, in the absence of evidence that the lungs, bowel, and skin compensated by increased excretion, meant that fluid was being stored in the body. The suggested method of correcting this state of hydration was to reduce the fluid intake, so that it never exceeded the urinary output of the day before. Accessory measures adopted in some of the cases with a view to reducing intracranial tension were the intravenous injection of glucose (40 c.cm. of a 20 per cent. solution) or magnesium sulphate (20 c.cm. of a 20 per cent. solution), and spinal drainage. These methods were only used if high blood pressure, headache, and dimness of vision were not quickly responding to reduced fluid intake. A standard diet was employed. Its calorie value was 1,500, and it contained 70 grams protein, 30 grams fat, 240 grams carbohydrate, and 3 grams salt. Beef or mutton, cod or hake, boiled puddings, bread-and-butter, tea, and cocoa were allowed. Meals were taken at 8 a.m., 12 noon, and 4 p.m., and a drink was given at 8 p.m. No eating or drinking between meals was allowed. When a patient was admitted a history was taken and a complete examination made. An arbitrary figure was chosen for fluid intake for the first twenty-four hours, from 600 c.cm. in a mild case down to *nil* for a severe case. All urine passed was collected and measured, and the amount recorded. A dose of mist. alba was given each morning before breakfast. On the morning after admission a catheter specimen of the urine was obtained and a simple enema given. A sample of the twenty-four-hour specimen was put in an Esbach tube each night. After the first day the amount of fluid allowed was equal to the urinary output for the previous day. If the patient was discharged undelivered she was instructed to keep to the diet and fluids taken in hospital; she still took the mist. alba every morning, and attended the ante-natal clinic weekly. If improvement was only temporary, or not adequate, labour was induced by the bougie method. Twenty-eight patients were primigravidae and eleven multigravidae. Medical treatment sufficed in thirty-six cases. In the other three—all primigravidae—labour was induced as improvement was not maintained. The treatment in favourable cases was followed by reduction of blood pressure to normal figures, disappearance of oedema, diminution of albumin, and cessation of headache, dimness of vision, dizziness, vomiting, and drowsiness. In all cases a healthy live child was born; in thirty-six instances the mother was cured, and in three symptoms recurred after partial relief. Despite the restricted fluid intake a progressive increase in the daily volume of urine occurred, lasting from four to ten days, after which the volume remained steady. This was equal to the volume of fluid which could be allowed without storage occurring. If the intake was increased beyond this figure there tended to be a recurrence of symptoms.

Mr. M. DATNOW (Liverpool) showed a lighted vaginal speculum of new design.

The following appointments have recently been made in the German faculties of medicine: Dr. M. Kirschnner, director of the surgical clinic of Tübingen University, professor of surgery at Heidelberg in succession to Geh. Rat Enderlen; Dr. Ernst Ruickoldt of Göttingen, professor of pharmacology at Rostock; Dr. R. Sirberk, professor of internal medicine at Heidelberg. Dr. Walter Kurten, lecturer on problems of race and heredity, has been nominated professor of internal medicine at Halle; Dr. B. Spiethoff of Jena, professor of dermatology at Leipzig; Dr. Kurt Goertler of Zürich, professor of anatomy in Hamburg, in succession to Professor H. Poll; and Dr. Gottfried Raestrup, professor of forensic medicine at Leipzig, in succession to Geh. Rat Kockel.

CORRESPONDENCE

The Milk Question

SIR,—In his letter in the *Journal* of April 21st (p. 727) Dr. W. S. Forbes, referring to the League's report on tuberculosis of bovine origin in Great Britain, reads into the conclusions of that report a meaning which was certainly not present in the minds of those who compiled it. He states: "The P.L.H. report suggests that milk from tubercle-free herds should be sold raw or pasteurized, which means that other infective organisms, whose presence is used as an argument for pasteurization, are adequately dealt with by clean methods: I am glad to find that the committee agrees with me in this." The reason why it was recommended that milk from tubercle-free herds should be sold raw or pasteurized was because the committee's terms of reference allowed them to deal only with tuberculosis. If milk-borne disease as a whole had been under consideration, then doubtless the advisability of submitting all milk to adequate heat treatment would have been pointed out.

When Dr. Forbes states: "An all-round clean milk means fewer cases of tuberculosis, despite the presence of tubercle bacilli," does he mean to say that clean milk containing tubercle bacilli is less infective than dirty milk containing the same number of tubercle bacilli, and if so will he be kind enough to bring forward the evidence on which this statement is based?—I am, etc.,

People's League of Health, W.I,
April 30th.

C. O. HAWTHORNE.

SIR,—Will you allow me to make a belated reply in correction of a statement made in Dr. Kitching's letter in the *Journal* of March 31st. The laboratory to which my letter in the *Times* of March 5th referred was the Research Institute in Animal Pathology of the Royal Veterinary College, working with a grant from "United Dairies." Dr. Kitching scolds me for not having specified the laboratory in my letter to the *Times*. The necessity for brevity was my reason for not doing so.

The brochure, "The Nation's Milk Supply," published by the United Dairies Laboratory Department, contained only a very short résumé of the experiment conducted at the Royal Veterinary College. The full report is published in the *Journal of the Society of Chemical Industry* (1933, lii, 379).

May I refer Dr. Kitching to the important letter in the *Times* of to-day, over the signature of Lord Dawson, conveying resolutions of the last comitia of the Royal College of Physicians (April 26th), in which the danger of supplying raw milk under present conditions is again stressed.—I am, etc.,

House of Commons, May 1st.

E. GRAHAM-LITTLE.

* We refer to Lord Dawson's letter on p. 810—
Ed. B.M.J.

Periodical Sterility

SIR,—The form in which "X," in his discussion of periodical sterility (*Journal*, April 21st, p. 740), records the time of menstruation and ovulation prompts us to submit a simple diagrammatic representation of the menstrual cycle which we have found useful when presenting the subject to students.

In the last three or four years much has been added to our knowledge of menstruation and of the occurrences which take place in the early days following fertilization of the ovum: so much, indeed, has been added that the bewildered student requires a framework on which the more elaborate structure may be built and explained to

him. The following scheme, of which simplicity, brevity, and approximate accuracy are the main features, enables the beginner to see at a glance the outstanding events in the cycle when pregnancy does and does not occur.

DIAGRAMMATIC REPRESENTATION OF MENSTRUAL CYCLE

Details can be elaborated when the important points have been mastered. Thereafter we proceed to describe fully endocrine activity, imbedding, and metabolism (maternal and foetal). Thus is the student introduced to the study of obstetrics.—We are, etc.,

J. M. MUNRO KERR.

University of Glasgow, April 22rd.

D. F. ANDERSON.

Insulin in the Early Morning

SIR,—In your issue of April 7th (p. 628) is an annotation on carbohydrate metabolism and liver function, in which the suggestion of Mollerstrom that a dose of insulin should be given very early in the morning is regarded with disfavour as being not without great practical inconvenience. It may therefore be of more than passing interest to state the experience of the Ministry of Pensions, whose cases have been under the care and treatment for many years of Dr. J. G. Willmore and other medical officers assisting him.

Almost without exception the cases of diabetes under treatment by the Ministry of Pensions are of considerable severity and of not less than fifteen years' standing, in that a man is only pensioned for diabetes if it be proved that the disease arose during—and/or by reason of military service during—the Great War. The few exceptions—not so much as to severity but as to duration—are those in whom the diabetic condition has supervened on long-continued suppuration, or constantly recurring "flares," of gunshot wounds. Up to four years ago great difficulty had been experienced in keeping the blood sugar values within normal limits between the early morning fasting blood sugar and the value at 12 noon. Very frequently the morning fasting blood sugar, taken as a routine practice at 7.30 a.m., was found to be far too high—in the neighbourhood of 0.2 per cent. In spite of massive doses of insulin given before breakfast a further hyperglycaemic rise would take place at 10 a.m., to be followed by a rapid fall to hypoglycaemic levels at noon. In other words, a violent oscillation took place between breakfast and lunch, which did not respond to large quantities of insulin given, in a single dose, twenty minutes before breakfast. On the other hand, there was hardly ever any difficulty in controlling the blood sugar

between 1 p.m. and bedtime. Increasing the evening dose, giving a small dose at bedtime, and waking the patient up in the middle of the night or in the small hours of the morning to give a dose of insulin were all tried. All that happened was that the patient became hypoglycaemic in the small hours of the morning, was given sugar and/or adrenaline to combat it, and his blood sugar taken at 7.30 o'clock next morning was higher than ever.

In common with those who have worked at all extensively on diabetes it had been noted that the critical time for a diabetic was always between waking and 12 noon, and it was therefore decided to try the effect of splitting the before-breakfast dose of insulin into a smaller fraction at 6 a.m. and a larger fraction just before breakfast at 8 a.m. It was found not only that the blood sugar taken at 7.30 a.m. was materially lower, but that the forenoon-swing from high to low was abolished; and in most cases it was found possible to attain the ideal of keeping the fasting and post-absorptive blood sugars somewhere below 0.1 per cent. and the absorptive (that is, after-breakfast rise) round about 0.15 per cent. Any tendency to hypoglycaemia between 11 a.m. and lunch is easily averted by the taking of one or two Rabinowitch equivalents—usually in the form of fruit or biscuits—at 11 a.m. as a routine practice. It was somewhat surprising, however, to find that the urine collected first thing in the morning (that is, secreted during the night) as well as that at 7.30 a.m., when the first blood sugar value was taken, was free from glucose. This suggested that the blood sugar value had not exceeded the renal threshold between the previous evening and the following 7.30 a.m. (This only happens, of course, provided that the renal threshold for glucose is not unduly low: curiously enough, a true diabetic may have an inconstant threshold, especially if thorough and prolonged insulinization has been effected.) The physiological explanation of this would seem to be that the blood sugar value does not rise, as had previously been supposed, during sleep, to reach a maximum when the patient wakes in the morning; but rather that endogenous glycconeogenesis occurs during sleep, that the carbohydrate so formed remains condensed in the liver as glycogen during sleep, and that it is only on the resumption of the waking phase of metabolic activity that glycogenolysis occurs with a rise in the blood sugar.

It seems rational to assume that the normal, non-diabetic person calls upon his liver to supply the necessary heat and power to enable him to get up and dress. The liver of a healthy person supplies only just as much hexose as is required: the liver of a diabetic, on the other hand, does not know when to stop, with the result that what one may term a "glycogenolytic crisis" takes place and hyperglycaemia ensues. It would seem, too, as though insulin were much more effective in preventing excessive hydrolysis than it is in recondensing a hexose once glycogenolysis has occurred. Otherwise it is difficult to explain why, in these cases, the large dose of insulin given before breakfast seemed to be unable to control the forenoon hyperglycaemia, and did not lower the blood sugar until the excess had been got rid of by the kidneys.

This plan of early morning dosage was found so successful that practically every patient who showed a high morning blood sugar has, during the past four years, been put on a dose of insulin for which he must be woken up. This routine, which was initiated by the Ministry four years ago, has been published and described in detail by a former medical officer of the Ministry of Pensions—Dr. Sidney Vatcher—in his recent thesis for the Cambridge M.D. In hospital the administration is, of course, easy, and it is given at 6 a.m. Outside hospital patients are advised to prepare their syringe with the

requisite dose overnight, to set their alarm clock to about half an hour or so before they normally wake up, to keep the previously sterilized needle protected by gauze soaked in spirit, and, when the alarm clock rouses them, to give themselves an injection. They can then either go to sleep again or read in bed until their normal time for getting up, which should not be less than half an hour after the insulin injection.

In practice few patients have complained of inconvenience; none have protested against the practice as inhuman; and the majority (including all the more intelligent) have been so impressed with the greater sense of well-being, and the very marked reduction in the total quantity of insulin necessary, that they have willingly and conscientiously co-operated. The ultimate decision as to whether the advantages outweigh the inconvenience must be one to be made by the patient himself.—I am, etc.,

Ministry of Pensions, April 23rd.

J. H. HEBB.

The Medical Curriculum

SIR.—The final report of the Committee on Medical Education was presented to the Council by Sir Henry Brackenbury on Wednesday, April 4th (*Supplement*, April 14th), and during the course of his remarks he made special reference to the position of physical medicine in the curriculum, and drew attention to the inclusion in this report of the following paragraph.

"It is clear that the teaching of the need for physical methods of treatment, of the occasions on which they should be used, and of their modes of action is no less important to the student than is the corresponding teaching with regard to drugs given in the course on pharmacology."

As chairman of the Physical Medicine Committee I should like to take an early opportunity of thanking the committee and the Council for taking this practical step in recognition of the advances that have been made during recent years in our knowledge of the treatment of disease by physical means. Such recognition will also receive the warm gratitude of all practitioners of physical medicine who have struggled so long against scepticism on the one side and the inroads of quackery on the other.

As physicists are reducing all substances in nature to problems in electrophysics, the time is probably not far distant when the physician in charge of physical medicine will take his place on the ordinary staff just as does the physician with a bent towards cardiology or biochemistry. The Council has now laid the foundation stone, and it is for the practitioners of physical medicine to erect a scientific building worthy of the support accorded to them.—I am, etc.,

London, W.1, April 25th.

C. B. HEALD.

SIR.—I hesitate to suggest any addition to the already burdened curriculum of the medical student, but seeing that it is again under review, and that up to the present I have never seen the point discussed, may I be allowed to draw attention to the importance in every form of practice of a sound knowledge of the subject of diet and of the methods of cooking food so as to render it suitable for the individual patient? From the first day he begins to practise the newly qualified practitioner will be consulted by patients of all ages on these points; but how can he give directions about a subject of which usually he is entirely ignorant? Bacon said: "There will be seldom use of physic in a sound or well-dieted body." Anyhow, the question of a suitable diet has to be settled, as a rule, long before that of drugs and medicaments, and

surely requires some *practical* knowledge. May I therefore plead that at least some provision for acquiring it should be made for the post-graduate, if impossible earlier?—I am, etc.,

LIONEL CALTHROP.

Radlett, April 24th.

SIR,—The report of the Committee on Medical Education devoted a page and a quarter to pre-registration subjects and dismissed the question of anaesthetics in less than seven lines.

"The administration of anaesthetics becomes more and more a speciality." Why? Because they, in their wisdom, insist on a medical student doing a minimum of nine months' chemistry, physics, and biology—not to mention botany—and one month's anaesthetics!

Considered in the cold light of reason this must be regarded as an absurdity. How much better to cut the nine months down to three, and use the remaining six in longer courses of anaesthetics, "district," fevers, insanity, and children—subjects of rather more importance to the general practitioner than vascular bundles and Wheatstone's bridge!—I am, etc.,

W. A. BELLAMY, M.R.C.S., L.R.C.P.

Sydenham, April 27th.

Injuries of the Knee-Joint

SIR,—I have read with interest the excellent article by Mr. T. P. McMurray on certain injuries of the knee-joint which appeared in the *Journal* of April 21st (p. 709).

May I be permitted to criticize his statement that internal lateral ligament sprains and tears should be treated by complete rest for a period of from fourteen to twenty-one days? I have seen many of these cases which have been completely rested for two to three weeks. The joint has lost its function of flexion, the muscles have wasted, and it requires between four to eight weeks' daily treatment, besides often a manipulation under an anaesthetic, before the knee is normal again. Is it not an important pathological principle for a ligament, when strained, to shorten either by replacement by fibrous tissue or by becoming bound down with adhesions? This point is so well demonstrated in sprains of the external lateral ligament of the ankle-joint. The movement of adduction and inversion is limited and painful in cases which have been rested completely, as the ligament has contracted and shortened as a result of the sprain. In sprains of the internal lateral ligament of the knee-joint, if the knee is gently flexed, the points of attachment of the ligament are approximated, so that no strain whatsoever can be thrown on the strained ligament. Therefore gentle active movements without weight-bearing are, in fact, beneficial, as they help the absorption of fluid, keep up the tone of the muscles, and prevent stiffness of the joint.

Another important point to realize is that in almost every case of internal lateral ligament sprain the knee automatically becomes flexed 5 to 10 degrees after a few days. The reason for this is that the posterior fibres of the ligament have shortened and contracted, and flex the joint to this degree. This means that extension is limited 5 to 10 degrees. As there is often, as well, a characteristic spring felt in trying to force extension, a diagnosis of a misplaced cartilage may be made, especially if bruising has spread into the surrounding tissues and tenderness can be felt over the cartilage. The importance of this point cannot be overestimated, as an operation otherwise may be undertaken unnecessarily. If these cases are treated with diathermy, faradic contractions, massage, and gentle active movements without weight-bearing, and gentle manipulative movements daily, they are completely right in most cases in from two to four weeks.

Mr. Fisher, in his book *Internal Derangements of the Knee-joint*, states:

"There can be no doubt that many practitioners err on the side of prolonged immobilization in the treatment of this injury. Carefully regulated movements play an important role in the absorption of intra-articular effusion and prevent the formation of adhesions. . . . The treatment of sprains by means of prolonged immobilization in splints is deeply rooted in the medical profession. It is a fruitful cause of muscular atrophy and stiff joints, upon which the bonesetter flourishes."

—I am, etc.,

London, W.1, April 27th.

W. ELTON TUCKER.

SIR,—It is presumptuous for one in general practice to criticize such a specialized paper as that of Mr. T. P. McMurray, as naturally the opportunity of seeing many of these cases is very limited. I am referring here to displacement of the semilunar cartilages. There is one statement, however, in this very interesting and instructive paper with which I cannot fully agree—namely, "these injuries *always* occur when the knee-joint is in a position of flexion." This statement is too sweeping to be universally applicable, and I know of two at least out of about a dozen cases where the knee joint was fully extended at the time of rupture, and the internal cartilage in each case was torn anteriorly, and laterally for part of its circumference, from its attachment, the joint remaining locked until the cartilage was removed.

The first was a man helping to lay tram rails. He was at one end of a rail, supporting it, when his foot became wedged in the angle of a "point," being firmly fixed thereby. The men at the other end of the rail began moving to the right, the injured man acting as a pivot. As they moved round, he was unable to turn round his foot and leg, but his body and femur were forcibly moved round. At this moment he felt something tearing in his joint, but he dared not drop the end of the rail through fear of it injuring him. He cried out with the pain, and when relieved fell down with the knee in the locked position.

The second instance was that of a hefty young footballer. Whilst running with the ball he was collared from behind and twisted clean round. At the moment his right foot was on the ground, and the studs in his boot prevented the foot and leg from turning in unison with the body and thigh. The weight of his own body, plus that of his opponent, applied to the powerful leverage of the femur, tore off his cartilage, the joint remaining locked until the cartilage was removed. In this case, also, the leg was straight, as it was the fixed foot which was on the ground.

It is quite reasonable to think that the leverage of the femur plus the weight of the body, plus the force applied is sufficient to grind off the cartilage even in the straight position; but the foot and leg must be fixed.—I am, etc.,

Leeds, April 29th.

J. STEWART.

Heredity and Mental Deficiency

SIR,—Professor Charles McNeill's interesting article in the *Journal* of March 31st (p. 584) as to the causation of mental deficiency has given prominence, apart from heredity, to such aetiological factors as environment, birth injury, etc. May one therefore suggest for consideration another—namely, the potential traumata of conception. As to mongolism, for instance, there is, among the less educated people of London, a widespread belief that the condition is produced by attempts at chemical contraception; and many an unhappy mother has, upon this ground, been subjected to the ribald or lugubrious comments of her neighbours. This may be of little importance, but I have on more than one occasion listened to the bitter plaint of a patient who had

CORRESPONDENCE

MAY 5, 1934]

become the father of a mongol, and who roundly attributed his misfortune to this cause; and in none of these cases was the man likely either to know of or to be influenced by such popular beliefs.

It appears to be universally accepted either that the chemical contraceptive completely exterminates all sperms or, in the event of failure, that some or all of them escape scathless. Why should this be so? It would seem to be equally reasonable to suppose that one sturdy spermatozoon, weathering the lethal waves, might be cast again on shore, thence to stagger his intoxicated way into the haven of an unsuspecting ovum. And who would say that the product of such a union would be normal? On the other hand, a case of mongolism has been described to me in which not only was the birth ardently desired by both parents, but was carefully "prepared for." It would be pertinent to inquire, as I did not at the time, whether the "preparation" took the favourite form of a "course of douching," and whether, therefore, the conception in question took place, as it were, under a libation of lysol. Again, is it not possible that the regular use of chemicals for any purpose might so permeate the female reproductive organs that no ovum could exist therein in an unpoisoned condition?

Consideration of these questions leads to others too numerous to mention. Theoretical as some of them may be, they require an answer, even if only happily to be eliminated. Few will dispute that the present state of our knowledge leaves much to be desired; and I am therefore of opinion that it would not be unprofitable to make a careful inquiry into the circumstances of conception in all cases of mental deficiency, slight and severe, and in all cases of physical developmental anomaly, whether separate or concurrent, and would make the suggestion to those whose special interest it is to evaluate the causes of human defect. The occurrence of mental deficiency and the practice of treating the maternal passages with chemicals of many kinds are equally old as far as medical history is concerned; and they are both increasing.—I am, etc.,

Kensington, W., April 21st.

SIR.—I can support Dr. Grundy's criticism (*Journal*, April 21st, p. 728) of Professor McNeil's paper in every detail. The exclusion of persons over 5 years of age rules out all but the lowest grades of mental defect, and it is only to be expected that such an investigation would lack evidence of heredity. If Professor McNeil extends his investigations to older children he will find a very different story.

It can be shown that the higher grades of mental deficiency tend to be associated with low social status and a high birth rate, whereas the lower grades tend to be associated with higher social status and a definitely lower birth rate. There is also a high death rate among the sibs in the former group. These facts are no doubt due partly to environmental causes; but it is surely not too great a stretch of the imagination to think that many of the sibs who have died might have proved to be grossly mentally defective if they had survived. Low-grade defectives are often of very poor physique, and considerable care and attention is necessary to enable them to survive. A mother of low social status would have great difficulty in rearing such low-grade children. I suggest that this is a very possible explanation of the failure to find many cases of low-grade deficiency with bad family history. They are absent because they have died.

Professor McNeil's experience with the mothers of the mentally defective children attending the Edinburgh Hos-

pital Clinic is very different from my own in Nottingham, where so many of the mothers of mentally defective children that have come under my observation are obviously of low intelligence. No fewer than 173 parents of 1,003 educable mental defectives and seventy-three parents of 414 idiots and imbeciles acknowledged to illiteracy, and in an area where the education has been efficient this is most suggestive. I feel confident that, as our records of mental deficiency become more complete, the more apparent will the hereditary factor become. Referring to the penultimate paragraph in Professor McNeil's paper, does he demand that the parents be mentally defective before he admits the likelihood of heredity?—I am, etc.,

A. A. E. NEWTH,
Senior Medical Officer, City of Nottingham
Education Committee.

Nottingham, April 24th.

Haemorrhage from Peritonsillar Abscess

SIR.—I was interested in Mr. T. G. Wilson's description (*Journal*, April 28th, p. 755) of a case of haemorrhage from a peritonsillar abscess. Mr. Wilson suggests that removal of the tonsil would be successful in these cases, and it proved so in a recent case of mine.

A similar type of patient was being exsanguinated by repeated haemorrhages from a quinsy which had ruptured spontaneously. Blood clot was being extruded from a small opening above the tonsil. Removal of the tonsil under a general anaesthetic was easy, as a dissection had been in the main done by a large clot lying between the tonsil and its bed. There was no difficulty in securing the bleeding-point, which was a fairly large arterial one. —I am, etc.,

Cheltenham, April 28th.

T. D. DEIGHTON.

Mind and Body

SIR.—The letter of Dr. Hugh Woods which appeared in your issue of February 24th (p. 356) has a strong flavour of the philosophy of nineteenth century science. I quote two continuous sentences from that letter: "We all know what the 'body' is, though we know much less about it than we would [sic] like. I do not even admit the existence of any actual thing called the 'mind.'" Now do we all know what the body is? And what does Dr. Woods mean by a "thing"?

In the issue of *Nature* for March 10th, 1934 (p. 341), there is a leading article on "Science and Philosophy" which medical men would do well to read. I quote from it the following passage as the science of the nineteenth century.

"The notion that to be real a thing must be of the same nature as a piece of matter, became the predominant axiom upon which was based any explanation of scientific results; and as matter can be seen and touched, whatever was real ought to be seen and touched, at least theoretically. . . . Yet, it is a curious fact that the further analysis of the objects perceived finally exploded the very 'reality' they represented.

"This is, however, the epic of the contemporary development of our knowledge. With matter considered as a hump in space-time and gradually vanishing into nothingness, the obvious and solid foundation of nineteenth century science has disappeared. . . . Not only does scientific thought affect the nature of the things it studies, but also matter itself becomes simply an appearance of the mental or spiritual unity which alone is real."

—I am, etc.,

P. D. STRACHAN, M.A., M.D.

Maseru, Basutoland, South Africa, April 4th.

Obituary

DAVID LECHMERE ANDERSON

Medical Officer of Health, Doncaster

With regret we record the death, on April 18th, of Dr. D. L. Anderson, at the age of 73. Born in Clackmannan he received his medical education at Edinburgh, where, in 1883, at the age of 21, he obtained the diplomas L.R.C.P. and S. and L.M. Ten years later he took the D.P.H. of Edinburgh and Glasgow. His first practice was at John-o'-Groat's, and his second at Peterhead, where he spent fifteen years. He was medical officer of health for Peterhead during his last three years there, and he held a similar office in the burgh of Ellon for six years. In 1902 he went to Doncaster as its first whole-time medical officer of health. From the start he had a great deal to do with tuberculosis, for the voluntary notification of this disease was already in operation, the small-pox hospital being then used for institutional treatment. When the Tuberculosis Act came into force Doncaster naturally became the centre for the treatment of patients from such towns as Dewsbury and Wakefield. In 1908 Dr. Anderson was appointed school inspector, and he helped to bring into being numerous school clinics for special treatment. He was regarded as an authority on miners' nystagmus; on the basis of his carefully compiled records of thousands of cases in the South Yorkshire coalfields he came to the conclusion that the disease was caused by the inadequate lighting in the mines and the abnormal postures adopted in colliery work, but that these conditions brought on nystagmus only in men suffering from, or predisposed to, common defects of vision, such as squint, ametropia, and astigmatism. He advocated that no boy with imperfect vision should be allowed to start work in a mine, arguing that in this way it should be possible to eliminate nystagmus. His theories received much support, and steps were taken to improve the lighting of mines, but this has not been universally accepted. Dr. Anderson was well known as a writer under the name of David Lechmere, and his books include *An Aesculapius of the North* and *In Deadly Peril*. Fond of racing, he had been one of the medical attendants at Doncaster races for many years. He was an excellent after-dinner speaker and a popular lecturer, a Freemason, one of the original members of the Danum Literary Society, and a former president of the Caledonian Society of Doncaster. His wife predeceased him about four months ago. He leaves a son, Dr. R. M. L. Anderson, who is in practice at Stainforth, near Doncaster.

WILLIAM HOWARD STURGE, M.D.

We regret to announce the death, on April 23rd, of Dr. Wm. Howard Sturge of Hoddesdon, as the result of a motor accident. Dr. Sturge was educated at the London Hospital, and qualified M.R.C.S., L.R.C.P. in 1891; he graduated in medicine at London University in 1892, and proceeded to his M.D. in 1893. After holding the resident posts of house-physician and house-surgeon at his old hospital, and of house-physician at the Brompton Chest Hospital, he went out to South Africa as civil surgeon to the South African Field Force. On his return to this country he settled down at Hoddesdon, where he was in general practice for many years. He was honorary physician to the Hertford County Hospital, and at the time of his death was the senior member of the staff.

Dr. Sturge was an old and active member of the B.M.A. Elected in 1894, forty years ago, he was a Representative at London in 1919, chairman of the East Hertfordshire Division 1929-30, and President of the Hertfordshire Branch at the time of his death. He took a great interest

in the administration of the Insurance Act, and was a member of the original Insurance Committee of Hertfordshire until he died. Other committees on which he served were the Panel Committee, of which he was also an original member, and the Medical Service Subcommittee. Always conscientious in anything he undertook, Dr. Sturge rarely missed a meeting of any of these bodies. In addition, he found time to take an active part in local public work, and was chairman of the Hoddesdon Urban District Council in 1928. Dr. Sturge's death will leave a gap in the profession in Hertfordshire that will be difficult to fill. He earned the respect and affection of all his colleagues, by whom he will be greatly missed.

CECIL WILLIAM CUNNINGTON, M.R.C.S., D.P.H.

The death has recently occurred, at the age of 79, of Dr. Cecil William Cunnington, at his residence at Kilburn, Dr. Cunnington, who was born in 1855, received the diploma of L.S.A. in 1882, and the M.R.C.S. and D.P.H. in 1893. He was a Warneford Scholar and an Associate of King's College. Dr. Cunnington had been a member of the British Medical Association for over forty years, and his was, until recently, a familiar figure at headquarters, as representative of the Hampstead Division on the Council of the Metropolitan Counties Branch. He was also for some years a member of the General Purposes Committee of the Branch, and had served on the Executive Committee of the Hampstead Division. Dr. Cunnington attended the annual meetings of the British Medical Association in the official capacity of Representative from 1915 to 1931 (except 1919). He had been a member of the Hampstead Borough Council since 1922, and in 1929 he was elected an alderman of that borough.

RICHARD LLEWELLYN JONES LLEWELLYN, M.B.

Consulting Physician, Royal Mineral Water Hospital, Bath

To the profound regret of a large number of friends Dr. Llewellyn Jones Llewellyn died in his sleep on April 19th, at the age of 64.

He was the son of Surgeon Major Morris Jones of Aberystwyth, and assumed the name of Llewellyn in 1911, when he married the Hon. Mrs. Crosse. He took the degree of M.B.Lond. in 1895, and from 1900 to 1902 was resident medical officer to the Bath Royal Mineral Water Hospital. His work at Bath filled him with interest in the problems of rheumatism and allied diseases, and he rapidly became an international authority in this field. He wrote, with the assistance of his brother, Mr. A. Bassett Jones, several important books on rheumatism and gout, the best known of which is perhaps *Arthritis Deformans*, while his articles on "The Gravity of Rheumatism as a Menace to National Efficiency," "Goitre in Relation to Rheumatism," and "The Endocrines and Rheumatic Fever" are standard references. He was an excellent writer, and could not only express his facts clearly but could make them sound interesting.

In 1912 he was appointed honorary physician to his old hospital at Bath, in 1913 he was elected a governor, and from 1915 to 1922 he served on the committee. In the latter year he was appointed consulting physician, a post which he filled until he died. During the war he became a member of the Central Appeals Tribunal of the Ministry of Pensions, where his specialist knowledge was of great value, but he came in contact with a much wider field of medicine. From his experience there he wrote "Malingering, or the Simulation of Disease" and "Pensions and the Principles of their Evaluation." His knowledge of rheumatic diseases, especially fibrositis, brought him a large consulting practice, from which he only recently retired. He held office in a large number of learned societies; he had been president of the Balneo-

logical and Climatological Section of the Royal Society of Medicine; a member of the Medical Research Council's Conference on Chronic Arthritis; chairman of the medical committee of the National Campaign for the Prevention and Relief of Heart Disease in Children; and vice-president of the British Committee on Rheumatism in the International Society of Medical Hydrology. He was also a member of the Board of Medicine in the Welsh National School of Medicine, and a fellow of the Royal Meteorological Society. When he died he was studying the causal significance of the absence of sunlight in rheumatism. The Hon. Mrs. Llewellyn survives him, with one daughter.

Universities and Colleges

UNIVERSITY OF OXFORD

At a congregation held on April 26th the degree of Doctor of Medicine (D.M.) was conferred on F. J. Sale.

UNIVERSITY OF CAMBRIDGE

At a congregation held on April 28th the following medical degrees were conferred:

M.D.—F. A. Richards, H. Taylor.
M.B., B.Chir.—A. Bowen-Davies.
M.B.—R. H. Fish, E. W. Taylor.
B.Chir.—P. R. Goodfellow, H. J. M. Robinson, W. F. Nicholson.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

A comitia of the Royal College of Physicians was held on April 26th, with the President, Lord Dawson of Penn, in the chair.

Fellowship

The following were elected Fellows of the College:

Thomas Gillman Moorhead, M.D. Dub., President of the Royal College of Physicians of Ireland; Duncan Graham, M.D. Toronto (Toronto); Patrick Playfair Laidlaw, F.R.S.; Geoffrey Eden, M.D. Camb. (Birmingham); Helen Marion Macpherson Mackay, M.D. Lond.; Walter Rupert Reynell, M.D. Oxf.; Richard Christopher Clarke, O.B.E., M.B. Bristol (Bristol); James Riddell Bell, M.D. Melb. (Melbourne); Thomas Sidney Nelson, M.B. Oxf.; William Stobie, O.B.E., M.D. Ed. (Oxford); Thomas Arthur Hughes, M.D. Dub. (Lahore); Claude Blaxland Levick, M.B. Syd.; Peter Knight McCowan, M.D. Ed. (Cardiff); Maurice Elgie Shaw, M.D. Oxf.; Sidney Campbell Dyke, M.D. Oxf. (Wolverhampton); William Moodie, M.D. St. Andrews; William Ernest Lloyd, M.D. Lond.; Victor John Frederick Lack, M.D. Lond.; Bernard Edward Schlesinger, M.D. Camb.; Alan Aird Moncrieff, M.D. Lond.; William Edmund Cooke, M.D. Lond.; Edward Revill Cullinan, M.D.; R. J. Camb.; Henry Cohen, M.D. Liverpool; Fitzgerald Collis, M.D. Camb. (Dublin); William Norwood East, M.D. Lond.; Robert Dick Gillespie, M.D. Glas.; Warrington Yorke, M.D. Liverpool; Fergus Robert Ferguson, M.D. Manch. (Manchester); Sir Penndrill Varner-Jones (Papworth), and John St. Clair Elkington, M.B. Camb.

Lord Dawson of Penn was re-elected representative of the College on the governing body of the British Post-Graduate Hospital and Medical School.

Membership

The following were admitted Members of the College:

Stanley George Browne, M.B. Lond., L.R.C.P.; William Allen Daley, M.D. Lond.; Ramanlal Ambefal Desai, M.B. Bombay, L.R.C.P.; Kenneth James Franklin, M.D. Oxf.; John Bishop Harman, L.R.C.P.; Arthur Landau, M.B. Capetown; Charles Roger Tessen Lane, M.B. Camb.; Gordon Alan Macdonald Lintott, M.B. Lond., L.R.C.P.; Leonard Joseph Alphonse Leewenthal, M.B. Liverpool; Harold Edward MacMahon, M.D. Western Univ., Ontario; Naguib Bey Mahfouz; Arthur John Rushton O'Brien, M.C., M.C., M.B. Ed.; Matthew Burrow Ray, D.S.O., M.D. Ed.; Eric Canullo Ritter, M.B. Glas.; Cuthbert Harry Rogerson, M.D. Lond., L.R.C.P.; Martin Richard Thomas, M.B. Lond., L.R.C.P.; Harold Williamson, O.B.E., M.D. Durh., L.R.C.P.; Alexander Louis Wainwright, M.B. Lond., L.R.C.P.; Barbara Edith Woodhead, M.B. Penn., L.R.C.P.

Licences

Licences to practise were granted to the following candidates:

A. K. Alfaria, A. R. Aem, Helen M. B. Alcock, E. C. Albhone, J. F. O. Amegatcher, J. B. Andessa, R. A. Andrews, M. Appelman, R. C. B. Barber, A. H. Bartlee, C. H. D. Bartlee, R. H. Bayler, R. A. Bonning, L. C. Bosfield, J. Boyle, Joyce M. Brackington, Edith I. R. Browne, J. C. H. Browne, A. G. Batters, N. A. Baxton, J. M. Buzzard, H. Cameron, Ruth M. Campbell, A. M. R. Cane, H. Taylor, C. M. Carlyle-Gall, R. Carpenter, R. M. Clarke, C. D. Clements, C. I. Cobbe, A. N. F. Critchley, I. H. J. Cress, T. M. Donald, H. H. Davies, D. W. A. De Garzon, Andrew P. Dence, Rosalind M. S. Derham, A. E. De Sa, A. M. Desmond, J. A. Diackla, Lynette Dowsett, F. W. Dunn, C. E. Elliott, H. J. Fenn, A. B. R. Finn, J. M. Fleming, P. A. Flood,

J. F. A. Forster, J. A. C. Franklin, Violet Fry, L. B. Furber, W. R. Gavin, S. W. Gillman, Bessie W. Goodwill, H. W. Gordon, R. I. N. Greaves, J. Greenhalgh, T. F. Greenwood, G. D. Hadley, G. J. Hamilton, W. H. Hamilton, J. W. Hannay, J. L. Hardman, J. H. T. Harrington, L. D. Harris, T. N. Hart, Violet C. Hart, A. E. M. Hartley, L. A. Hawkins, Barbara D. F. Hay-Cooper, J. N. Heales, D. F. Heath, R. R. Henderson, T. S. Heslop, R. Hill, I. W. Hockley, N. T. Holden, R. D. Holloway, M. H. Hosny, A. G. Hounsflow, D. A. Hovenden, H. G. Howitt, G. B. Hughes, N. G. Hulbert, J. A. C. Hunter, D. B. Hyslop, R. S. Illingworth, A. Innes, J. E. Jameson, C. C. Jeffery, B. S. Jones, I. D. Jones, A. C. Kannar, H. R. Kasday, L. M. Kelly, R. L. Kerr, M. A. Khan, J. Kingston, J. W. J. Knowles, Hilda I. Lanceley, K. A. Latter, A. M. Lester, T. Levitt, Margaret M. C. Louden, D. Lubin, K. Lumsden, W. D. F. Lytle, W. M. Macleod, I. Magdi, T. F. Malcolm, K. W. Martin, L. C. Martin, J. D. Martin-Jones, S. P. Mason, H. B. May, Queenie I. E. May, N. H. Merchant, Lida O. Meredith, W. G. Q. Mills, R. H. Moodie, J. N. Morris, L. O. Mountford, D. J. M. Moynahan, J. H. Neal, G. P. Neogv, A. Orlek, N. C. Oswald, B. H. Page, C. G. Parsons, J. E. G. Pearson, D. S. Piper, G. T. Pitts, C. H. G. Price, R. E. A. Price, Sylvia W. Pyddoke, S. Rameshwar, T. A. Ratcliffe, K. B. Rogers, G. H. Saunders, K. G. Seager, B. Selwyn, A. I. Shaw, J. G. Sheldon, T. L. H. Shore, H. S. Shucksmith, M. Shun-Shin, G. E. T. Soden, H. G. Stanton, W. J. Stokes, G. L. R. Tapsall, W. P. McK. Teller, Elizabeth J. McQ. Thomas, A. S. Till, G. C. Tooth, Elsie E. Vincent, J. H. Walters, W. F. Walton, C. W. Warne, C. R. H. Weekes, Elizabeth B. White, P. A. Wilkinson, M. Williams, J. W. Wishart, Audrey R. Wood, O. H. M. Woodbridge, A. R. C. Young.

The names of the recipients of the Diploma in Tropical Medicine and Hygiene, conferred jointly with the Royal College of Surgeons, were printed in our issue of April 21st (p. 734).

The Diploma in Gynaecology and Obstetrics was granted jointly with the Royal College of Surgeons to K. S. Jayakar.

BRITISH COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

The quarterly meeting of the Council was held at the College House on April 27th, with the President, Dr. J. S. Fairbairn, in the chair.

The following were elected to the Membership of the College: Agnes Marshall Cowan (Manchester), Charles Leopold Granville Chapman (Grimsby).

The President formally admitted to the Fellowship of the College Lieut.-Colonel Duncan Courtts (India), Lieut.-Colonel Peter Fleming Gow (India), Professor Gordon Grant (Johannesburg), Lieut.-Colonel Sydney Nuttall Hayes (India), Major Maurice Lawrence Treston (India), and James Hayward Willett (Liverpool).

The following were admitted to the Membership: Margaret Emily Anderson, Gavin Stiell Brown, John Lloyd Davies, Charlotte Ann Douglas, Gwyneth Griffith, Kathleen Marguerite Douglas Harding, Jocelyn Adelaide Medway Moore, Percy Peltz, John Marshall Scott, Arthur Joseph Wrigley.

A silver mace was presented to the College by the Gynaecological Club.

The annual general meeting of the College was held at the College House on April 27th. The President, Dr. J. S. Fairbairn, was in the chair, and thirty-eight Fellows and Members were present. The annual report of the Council and financial statement were adopted. Messrs. Barton, Mayhew and Co. were elected auditors for the ensuing year.

UNIVERSITY OF DUBLIN

TRINITY COLLEGE

At the first summer commencements, held on April 25th, the following degrees were conferred:

M.D.—W. G. Gallagher, F. M. Hilliard.
M.B., B.Ch., B.A.O.—I. A. Mallie.

The Services

NAVAL COMPASSIONATE FUND

At the quarterly meeting of the directors of the Naval Medical Compassionate Fund, held on April 19th, Surgeon Vice-Admiral Sir Reginald Bond, K.C.B., K.H.P., Medical Director-General of the Navy, in the chair, the sum of £235 was distributed among the several applicants.

DEATHS IN THE SERVICES

Captain Edward Barton Eadie, Indian Medical Service, died at Weston-super-Mare on February 5th, a few days before his thirty-fourth birthday. He was born on February 17th, 1899, and was educated at Bristol University, where he graduated M.B., Ch.B. in 1924. After filling the posts of resident medical officer at Cossham Memorial Hospital and resident obstetrical officer at Bristol Royal Infirmary he entered the I.M.S. as lieutenant on August 27th, 1929, and became captain three years later.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

The Betting and Lotteries Bill was read a second time by the House of Lords on May 1st without a division. A report of the debate appears below.

The House of Commons this week resumed discussion on the Unemployment Bill. The House again went into committee on Clause 19, and Mr. Neville Chamberlain proposed a reduction in the future payments to be made to the Treasury as interest on the debt of the Unemployment Insurance Fund.

The Road Traffic Bill is before a Standing Committee of the House of Commons, which will not consider for some time the amendments proposing compensation to doctors and to hospitals treating road accidents. These amendments will probably be moved as new clauses at the end of the committee stage. Conversations about them are proceeding between medical Members of Parliament and the Minister of Transport.

Sir Francis Fremantle has taken up Lord Dawson of Penn's Contraceptives Bill, sent from the Lords to the Commons, and has put down its second reading for May 7th. The Government has not promised facilities for this Bill.

The Royal Assent was given on April 26th to the Army and Air Force (Annual) Bill.

In the House of Lords, on April 30th, the Firearms Act (1920) Amendment Bill passed through committee.

In the House of Lords, on May 1st, the South Devon and East Cornwall Hospital, Plymouth, Royal Albert Hospital, Devonport, and Central Hospital, Plymouth (Amalgamation, etc.) Bill was read the third time and passed, and the South Downs Preservation Bill was read the second time.

The Employers' Liability Bill, introduced by Sir Walter Greaves-Lord, came before a House of Commons committee on May 1st, and was withdrawn.

Lotteries Bill

The MARQUESS OF LONDONERRY moved the second reading of the Betting and Lotteries Bill in the House of Lords on April 26th. He said that when the Royal Commission of 1932 was set up new factors had brought about social mischief which called for urgent remedies. These included the growth of lotteries, particularly of lotteries promoted abroad, and the exploitation of the population through the introduction of greyhound racing. The Royal Commission presented unanimous reports in January and June, 1933, covering the whole field of lotteries, betting, gambling, and cognate matters. The Government had decided to confine the present Bill to the more urgent problems—betting on the course, the legalization of the totalisator on greyhound tracks, lotteries, and certain competitions of mixed skill and chance. In respect of Part I of the Bill, which dealt with betting, the Government was satisfied that the provision of facilities for continuous betting on greyhound racing tracks had undesirable social consequences. The Royal Commission called attention to a general deterioration of character among young persons in poor neighbourhoods from night betting on greyhound races. Among other provisions, Part I of the Bill prohibited betting on a track with a young person under the age of 17 years.

Turning to Part II of the Bill, Lord Londonderry said that under the existing law all lotteries were unlawful unless expressly authorized by Act of Parliament, but an administrative practice had grown up in England and Wales under which the police did not set the criminal law in motion against private lotteries confined to members of a genuine club or society, or against small public lotteries, such as raffles at bazaars. A new situation had arisen from the sale in the United Kingdom of tickets in lotteries promoted abroad, notably the Irish Hospitals Trust sweepstakes. Ever since the introduction of these sweepstakes there had been an agitation for the legalization of large lotteries for charitable and

other objects. So far, Parliament had set its face against any relaxation of the existing law, and maintained the prohibition of all forms of lotteries, whether promoted for charitable or other objects. The Royal Commission approached the subject of lotteries from the point of view that present circumstances seemed to call for a considerable relaxation of the existing prohibition of large-scale lotteries in this country. After close consideration of the subject, it reached the conclusion that a relaxation of the existing prohibition of large lotteries was undesirable and not called for. The Government had also given independent consideration to the question of the legalization of large lotteries in this country. In addition, the Government had studied the views expressed in the debate in the House of Lords on November 30th, 1933, and was in agreement with the conclusion of the Royal Commission—that large-scale lotteries, whether promoted by the State for the direct benefit of the Exchequer, or by a statutory board for charitable objects, or by individual charities under a system of permits, were socially undesirable.

Lord Londonderry said the Royal Commission questioned whether in the long run voluntary hospitals in the United Kingdom would benefit by participation in the proceeds of lotteries. He himself, as a president of two hospitals, was convinced that the adoption of the system of public lotteries for the support of British hospitals would be disastrous. The total receipts of 1,014 British hospitals for the year 1930 was over £15,500,000. Unless the total subscriptions to lotteries amounted to a very large figure the proceeds would not be a material factor in hospital finance. He was also of opinion that it would be calamitous to this country if, by encouraging hospitals to derive their finances from the proceeds of lotteries, hospitals were to lose that element of personal service and personal interest which the present voluntary system achieved. If the promotion of large lotteries in this country was prohibited, the prohibition of the sale of foreign lottery tickets was a necessary corollary.

VISCOUNT BERTIE OF THAME moved the rejection of the Bill. He asked what mandate there was for it. Lord SANDERSON welcomed the proposals dealing with lottery and sweepstakes tickets, and congratulated the Government for resisting the demand to legalize State and other forms of lotteries. The DUKE OF SUTHERLAND said nobody wished hospitals to be dependent for their funds on sweepstakes or lotteries if they did not so wish, but a national sweepstake, licensed and controlled by the Government, would benefit medical research and the National Exchequer. The man in the street wanted to be allowed to take tickets in a lottery. The DUKE OF ATHOLL said that in 1931 the receipts of the voluntary hospitals were £15,108,855, of which £14,501,184 was spent. In London there was a deficit of £101,453; in the English provinces a deficit of £51,907, but in Scotland a surplus of £206,326 and in Ireland a surplus of £554,705. This latter figure—namely, £554,705—represented Irish sweepstake money for Irish hospitals. The £15,108,855 included interest from investments, legacies, and so forth, as well as the voluntary contributions of the current year. Sir Charles Harris, in the *Hospital Year Book*, had said that broadly the maintenance surplus was applied in making good the capital deficiency. It would relieve those responsible for the finances of the hospitals if they only had to be responsible for maintenance, and if the money for capital expenditure and medical research could be found from other sources. With regard to the Irish sweepstakes for the eleven between November, 1930, and March, 1934, the total subscribed, as shown in the accounts, was £31,300,874. Of this, taking the figure of 83 per cent. calculated by the Royal Commission on Lotteries to be the amount subscribed from Great Britain, £25,975,000 was subscribed in this country. They must add £21,331,000, as representing the undisclosed British subscriptions, making a total of £47,310,000, which, after deducting £13,769,000 returned in prize money to this country—on the basis of 53 per cent. given by the Royal Commission—resulted in a total of £33,541,000 lost to Great Britain in forty-one months, or £818,000 per month, or an average of £9,816,000 per year, representing about two and a half times the amount of the entire annual voluntary subscriptions to British hospitals.

The debate was resumed on May 1st. The BISHOP OF WINCHESTER said that in the previous debate it was shown that by far the larger part of the money raised for hospitals

by lotteries never reached the hospitals. Lord SOMERLEYTON said that there was still a general opinion that voluntary hospitals were in danger, and ought to be supported by sweepstakes or lotteries. Hospitals in this country were in a flourishing condition if they considered the bad times through which the country had passed in the last few years. In 1931 the aggregate surplus for the London hospitals was £76,000, and in 1932 £101,000. The figures for last year would probably be better still. In 1930 voluntary gifts to hospitals amounted to £12,274,000, and in 1931 to £11,568,000. In 1931 the total income was £13,741,000. Those voluntary gifts would be jeopardized by sweepstakes and lotteries.

The EARL OF FEVERSHAM said that the Government agreed with the Royal Commission as to the inadvisability of State lotteries. If the State inaugurated or tolerated the inception of lotteries to raise money for hospitals there would not be the same individual interest that was now taken by private persons in the maintenance of hospitals.

Lord BERTIE withdrew his motion for the rejection of the Bill, and the measure was read a second time.

Duty on Arc Lamp Carbons

During consideration of the Budget resolutions on report stage in the House of Commons, on April 26th, Sir PERCY HARRIS opened a discussion on the Government proposal that from April 18th the customs duty leviable on imported arc lamp carbons should be increased. The duty under the Safeguarding of Industries Act was 1s. per lb.; the resolution increased this to 5s. per lb. for carbons exceeding 14 millimetres in diameter, and to 7s. 6d. per lb. for other carbons. Sir Percy said most up-to-date private hospitals and some public hospitals were equipped with arc lamps for therapeutic treatment. To get satisfactory results in treatment of skin diseases, such as lupus, it was essential to have efficient carbons. The consulting engineer of St. Bartholomew's Hospital had made experiments in order to use British carbons, but had not met with success. A specially manufactured carbon was needed in the hospitals to provide the ultra-violet rays. An inefficient carbon gave variation. This engineer said it would be cheaper to buy British carbons, but whereas the British carbon lasted four to six hours, the foreign carbon lasted twelve hours. In 1933 this hospital used 516 lb. of carbons, valued at £180; the extra duty would cost them over £100. Members would see what a tax this would be on all the hospitals which were applying the treatment. In spite of the extra duty the hospitals would still require to import the foreign article if successful results were to be obtained. The Chancellor of the Exchequer should have consulted the medical profession before putting on this new tax. Sir ROBERT HAMILTON seconded the amendment, and also alluded to the case of St. Bartholomew's. Dr BURGIN, replying for the Government, said one great London hospital joined in the statement that the Continental carbons were required. Further inquiry showed that one department of the hospital thought it necessary to have Continental carbons while another department had for years used British carbons. The British carbon was not inferior. He had a list of 300 hospitals, including most of the well-known London ones, to which British carbons were supplied now, and had been supplied for years. These carbons were used to provide a stable and definite light during operations and other therapeutic work. The Finsen lamp was often supplied from Scandinavia, but was fitted with carbons supplied from this country.

Sir Percy Harris's amendment was defeated by 237 to 54.

Working Conditions in Distributive Trades

On April 30th Sir JOHN GILMOUR moved the second reading of the Shops Bill, which has already passed the House of Lords. He said that much remained to be done since the passing of the Children and Young Persons Act, 1933, to prevent employment putting an undue strain on the health of young people, and the purpose of the Bill was to tackle that problem. Its objects were twofold. First, it contained provisions for regulating the hours of young persons between 14 and 18 years of age employed in the distributive trades.

Secondly, it provided for improvement, in various directions, of conditions affecting the health and comfort of all shopworkers, of whatever age, employed in retail and wholesale shops and warehouses. Clause 1 fixed the normal maximum working hours at forty-eight in any week, exclusive of meal intervals. The Bill also secured an elasticity, which was necessary in certain cases, by providing: (1) for a limited amount of overtime; (2) that in certain special trades the hours might be averaged over a period of two or three weeks; and (3) for the general operation, during a transitional period, of a rather higher normal weekly maximum of hours. It was provided that, until the end of 1936, the normal weekly maximum hours should be fifty-two instead of forty-eight, with corresponding reduction in overtime. Under the Bill the distributive trades were having considerable restrictions placed on them, and those restrictions would demand certain adjustments. It was reasonable, therefore, that there should be time to deal with them. The provisions in Clause 3 were designed to secure a proper night's rest to all young persons, the staple requirement being at least eleven consecutive hours. The privilege of a weekly half-holiday and a statutory meal interval was now to be given to all young persons employed about the business of the retail and wholesale establishments covered by the Bill. The Select Committee on Shop Assistants, which reported in 1931, stated that, while health and welfare conditions in shops had changed substantially for the better in recent years, others still existed in shops which called for very considerable improvement, as, for example, in heating arrangements, ventilation and lighting, and the provision of suitable and adequate sanitary conveniences and washing facilities. That problem, which needed careful attention, was dealt with in Clause 10, under which the local authority was given discretion to serve the statutory notice requiring a remedy of any contravention of the requirements on either owner or occupier. Mr. RHYS DAVIES welcomed the Bill, particularly the provisions for the health and comfort of the shopworkers. The Bill, he said, did nothing to deal with the terribly low wages of boys and girls in the distributive trades. The long hours permitted under the spread-over system for the catering trade and garages should also be reduced. Mr. LUNN urged that the transitional period was too long, and that the forty-eight-hour week should be brought into operation at once.

The Bill was read a second time and committed to a standing committee.

The Warren Fisher Report

On May 1st Mr. HORS-BELLISHA informed Captain Elliston that the Government had adopted the recommendations of the Warren Fisher Committee in their application to the medical branches of the Army and Royal Air Force. As regarded the Royal Navy, it had been considered necessary to modify the scheme recommended in certain particulars. The changes would take effect from May 1st, and details would be found in Orders which were on the point of publication.

Water Supplies Bill

In the House of Commons, on April 30th, the Water Supplies (Exceptional Shortage Orders) Bill passed through the report stage. Sir HILTON YOUNG, in moving the third reading, referred to the position to date of the water supplies of the country in relation to the recent rainfall. He said that, although there had been a welcome change, it had not been so substantial as to make the measure unnecessary. We had not had more than normal rains, and we should have to have abnormal rains to relieve us from the necessity for the emergency measures. He had received returns from nine of the places where the difficulties were greatest, and in only one had there been such a large increase as to put a new face on the situation. In another place there had been a substantial improvement; in six others there had been only a slight improvement or a mere maintenance of the original position when the Bill was introduced, and in one the situation, in spite of the rain, had become worse. That showed how far-reaching the problem was. The Government still looked to the country as a whole for its co-operation in protecting itself against the evil consequences of the drought. It looked to the water undertakers to

consider well in advance what alleviating measures could be taken, with the assistance of the Bill, and to put them into force. It also looked to the general public, who must still do all it could to exercise care and moderation in the use of water.

The Bill was read the third time. Later in the day it was introduced in the House of Lords and read a first time.

The Punishment of Juvenile Offenders.—Replying to Mr. Bernays, on April 26th, Sir JOHN GILMOUR stated that in a circular letter about the Children and Young Persons Act of 1933, sent by the Home Office to courts of summary jurisdiction in August last, it was pointed out that, while in the new Act the power to order a child to be whipped was retained, the practice of the most experienced juvenile courts for many years showed that these courts rarely or never needed to exercise this power. It should be for the discretion of the justices to decide when use should be made of any form of penalty authorized by law.

Medical News

The annual meeting and dinner of the University of London Medical Graduates Society will be held at the Langham Hotel, W., on Tuesday, May 8th, at 7 for 7.30 p.m. Lady Barrett will preside at the commencement, and subsequently the incoming president. Members may bring guests, who must be medical graduates of the university. Applications for tickets (12s. 6d. each) should be sent to the honorary secretaries, 11, Chandos Street, W.1, not later than May 5th.

The ninety-first half-yearly dinner of the Aberdeen University Club, London, will be held at the Trocadero Restaurant at 7 for 7.30 p.m. on Thursday, May 17th, under the chairmanship of Professor Alexander Low, M.D. Secretary's address: 16, Tregunter Road, S.W.10.

The annual supper of the Paddington Medical Society will be held at the Cumberland Hotel, Marble Arch, W., on Thursday, May 17th, at 8.45 for 9 p.m. The guests of the evening will be Dr. G. C. Anderson (Medical Secretary, British Medical Association) and Mrs. Anderson, and Dr. and Mrs. E. Morland.

A reception will be held by the Royal Society of Medicine at 1, Wimpole Street, on Wednesday, May 30th, when Fellows and their friends will be received in the library at 8.30 p.m. by the President and Mrs. Warren Low. At 9.15 p.m. an address will be given by Professor William Wright, entitled "Richard III and the Princes in the Tower." Admission is by ticket only, obtainable from the secretary.

The eighth annual medical reunion of the University College (late Queen's College), Galway, North of England, and Midlands Alumni Association will be held at the Queen's Hotel, Piccadilly, Manchester, on Saturday, May 12th, at 7.30 p.m.—dinner at 8. The subscription is one guinea, which includes the dinner, cost of organization, printing, etc. Graduates who have not received notice of the reunion should notify their intention of attending to Dr. P. J. Webb, 127, Rochdale Road, Harpurhey, Manchester, 9.

Professor Charles Singer, M.D., F.R.C.P., will deliver the annual oration on "The Contrast Between Ancient and Modern Science" at the London Jewish Hospital Medical Society, Stepney Green, E., on Thursday, May 10th, at 4 p.m.

The fifth Hugh Owen Thomas Memorial Lecture will be given in the Liverpool Medical Institution on Thursday, May 10th, at 4.30 p.m., by Professor John Fraser, on "Lipoid Granulomatosis of Bone." Tea at 4 p.m.

The Fellowship of Medicine (1, Wimpole Street, W.) announces that Dr. Clark-Kennedy will lecture on digitalis, at 11, Chandos Street, on May 8th, at 2.30 p.m. The next lecture-demonstration, dealing with quinine, will take place on Tuesday, May 15th. The fifth of the demonstrations on blood diseases, by Dr. H. L. Marriott, at

the National Temperance Hospital, will take place on May 12th, at 3 p.m. A fortnight's course in urology, for advanced post-graduates, will be given at St. Peter's Hospital from May 7th to 19th. Other forthcoming courses include: diseases of the chest, a week-end course at the Brompton Hospital, May 26th and 27th; a week's course in chest diseases, at the Victoria Park Hospital, May 28th to June 2nd; a fortnight's course in gynaecology, at the Chelsea Hospital, May 28th to June 9th; and a month's course in venereal disease, at the London Lock Hospital, May 28th to June 23rd. Individual clinics in various branches of medicine and surgery are available daily for those who cannot find time to attend a full course.

The German Pathological Society will hold its annual meetings at Rostock from May 23rd to 25th, under the presidency of Dr. W. Hueck of Leipzig. The subject for discussion will be gliomata, introduced by Professor Folke-Henschen of Stockholm.

An international congress of medical motorists will be held at Utrecht from May 20th to 24th, when the following papers, among others, will be read: "The Rights of Priority in Circulation on the Roads and Diminution of Taxes for Medical Motorists," by Rudolf Keil of Regensburg; "International Medical Requirements for Permission to Drive," by Hochsinger of Vienna; "The Organization of First Aid in Holland," by Prins of Utrecht; "Diminution of the Expenses of Medical Automobilism," by Westermayer of Dresden; and "Special Insurance of Medical Motorists in Denmark," by L. Martin of Middelafahrt. Further information can be obtained from M. G. A. Prins, Utrecht.

Dr. Thomas Roberts Griffiths of Kidwelly, who died on January 17th, left estate of the gross value of £22,257, with net personalty £13,443. He bequeathed the residue of the property to the British Empire Cancer Campaign and Dr. Barnardo's Homes.

The New York University and Bellevue Hospital Medical College has opened a special out-patient department for the treatment of industrial diseases such as silicosis, lead poisoning, professional dermatoses, and benzol poisoning.

ROYAL ARMY MEDICAL CORPS

NEW CONDITIONS FOR OFFICERS

A Royal Warrant published in a special Army Order promulgates the new conditions under which commissions in the Royal Army Medical Corps will in future be granted to medical men. These conditions give effect to the recommendations in the Report of the Fisher Committee on the Medical Branches of the Defence Services issued last year, in so far as they affect the Army. Entry will be by short-service commissions for five years, at the end of which time officers will be eligible for a gratuity of £1,000, unless selected for permanent commissions. Promotion will be to captain after one year and to major after ten years' service, instead of after three and a half years and twelve years respectively. The increments of pay, which have hitherto been given in these ranks after eight and ten years in the case of captains, and after fifteen, eighteen, and twenty years in the case of majors, will in future be given to captains after six and eight years, and to majors after thirteen, sixteen, and eighteen years. The establishment of permanent officers will be maintained at a number which it is calculated will ensure promotion to lieutenant-colonel and colonel after approximately seventeen and twenty-five years' service respectively. In the past the rank of lieutenant-colonel has been attained after about twenty-four years' service, and that of colonel after about twenty-nine years' service. Ample professional opportunities exist, as the duties of officers of the Royal Army Medical Corps not only comprise the medical care of the soldier, but also extend to the medical care of their wives and families, and officers are encouraged to specialize in selected subjects. Full particulars of the conditions can be obtained either by personal application, or by letter addressed to the Assistant Director-General, Army Medical Services, War Office, London, S.W.1. A selection of candidates will be made about the middle of June.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, *Athlough Westcent, London.*

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate Westcent, London.*

MEDICAL SECRETARY, *Medisecra Westcent, London.*

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drum-hugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

An Unusual Sign in Diabetes Mellitus

Dr. S. VATCHER (Barnet) writes: In reply to Dr. Fawcett's inquiry (*Journal*, April 28th, p. 785) I may state that in the course of routine examinations, while I was in charge of the Ministry of Pensions Diabetic Clinic, I noted in about fifteen cases out of 300 investigated that the first sign which the patient had noticed had been a white powdery deposit on his trousers, underclothes, or boots.

Dr. H. J. STARLING (Norwich) writes: I have frequently met with this deposit of sugar on the boots of male diabetic out-patients, and it has struck me how careless such men must be in the final stages of micturition. Quite a few diabetics come to my out-patient department on account of this white boot deposit. In the females the complaint is sometimes of the stiffness of their undergarments.

"R. C. C." (Petersfield) writes: I was asked by an elderly glycosuric patient the other day to test a specimen of his water, and when I told him it was sugar-free he replied, "I thought so, as I have no white powder on my boots." In his younger days he used to gauge his trouble by the encrustations on his boots!

Income Tax

Amount of Liability

"BLIMEY," writing from abroad, asks what will be his position as regards income tax with an income of £560, all derived from dividends.

* If unmarried our correspondent's liability will be as follows:

On the first £100
On the next £175 at 2s. 6d.
On the balance of £225 at 4s. 6d.
									£70 6 3

If he is married the "first" section is £150, and the amount payable will be £12 10s. less.

Assistant—Cash Allowance for Rooms, etc.

"B. R. C." was employed at a salary plus free lodging and housekeeper's services. After a few years this arrangement was changed, and in lieu of those benefits he receives a cash allowance of £52 a year. Must he include this as an assessable emolument?

* Yes. The other arrangement was of a special type. "B. R. C." now receives a total cash remuneration (like most employees), and is liable on the full amount. The previous year's basis applies, so that if the change was made from, say, the end of September, 1934, he will be liable to include one-half of £52 = £26 in his return for the year commencing April 5th, 1934.

LETTERS, NOTES, ETC.

Sedatives in Lobar Pneumonia

"NEST" writes: Professor Arthur J. Hall, in his article on "Bodily Diseases in Mental Disorders" in the *Journal* of January 27th, when dealing with pneumonia in mental patients, draws attention to the marked effect of restful nights, so noteworthy. He suggests that "a free use of effective sedatives may do more good than harm." This reminds me of the teaching of Dr. G. W. Ballour, the eminent heart specialist of Edinburgh, who some fifty years ago strongly advocated chloral hydrate in this disease. In my youthful days I ventured in this way, with what appeared excellent effect. Unfortunately youth's rashness mellowed into middle-age timidity, and I listened to the sage advice of the vaccine therapist, who offered me the crumbs of comfort that dropped from his bench. No doubt typing and Felton have promoted the literature of the subject, but I wonder whether the comfort of the patient has yet had its therapeutic due.

Tannic Acid Dressing

Dr. A. H. BENNETT (Northwich) writes: It may be of some interest to readers to hear of a very simple method which I use to apply tannic acid to burns. Messrs. Woolly and Sons of Manchester have prepared for me surgical lint impregnated with tannic acid and mercuric chloride in such proportions that when the lint is thoroughly saturated with water it contains a 2 per cent. solution of tannic acid and a 1 in 2,000 solution of mercuric chloride. This affords a simple and convenient means of applying tannic acid to a burn, as suggested by Mr. Mitchiner, both as a first-aid and as a permanent dressing. I have successfully used this method in a number of cases, and the results have compared very favourably with those of others treated with fresh solution made from tablets.

The Cause of Hyperpiesia

Dr. G. ARSOUR STEPHENS (Swansea) writes: May I be allowed to state that the value of Dr. Donnison's article (*Journal*, April 21st, p. 704) would have been greatly increased had he (1) given us a definition of what he understands by "hyperpiesia," and (2) stated the size of the sphygmomanometer armlets used by him for his investigation. The estimations of the blood pressure vary with the size of the armlet, from 150 mm. Hg as normal with a two-inch armlet, to 120 mm. Hg with one four inches in width. A definition is necessary so that readers may have a good idea of what is in the mind of the writer when he talks about systolic and diastolic pressures and how they are related to one another. If the diastolic be the pressure on the blood in the arteries which the systolic pressure of the heart stroke has to overcome there must obviously be a normal ratio of greatest efficiency. By my method, using a two-inch armlet, the systolic pressure is normally 150 mm. Hg, and the basic pressure is 50 mm. Hg—that is, the most efficient ratio is three to one. When the ratio becomes two to one or lower, either as 150/80 or 90/50, it is obvious that the heart is pumping against an increased force and is working under great difficulty. The raising of the basic from 50 to 80, or the dropping of the systolic from 150 to 90, disturbs the normal ratio to apparently about the same extent, but the cause is greatly different in each case. The raising of the basic from 50 to 80 mm. would probably be due to the presence of toxins in the blood, whereas the lowering of the systolic from 150 to 90 mm. might be due to some nervous disturbance. The treatment in each case would therefore be quite different.

Corrigenda

Leucocyte Counts

Dr. JAMES ADAM (Glasgow) writes: In my letter in the *Journal* of April 28th (p. 775), the phrase "injection of urea" in regard to increase of eosinophils should read "ingestion of urea."

Health of the Navy 150 Years Ago

Surgeon Captain B. PICKERING PICK, Editor, *Journal of the Royal Naval Medical Service*, writes (from Gosport): A mistake occurred in the article entitled "The Health of the Navy 150 Years Ago" (*Journal*, April 28th, p. 760). The abstract from the *Journal of the Royal Naval Medical Service* was by R. R. James, and not R. R. Jones, as stated.

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 48, 46, 47, 48, 49, and 52 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 50 and 51. A short summary of vacant posts notified in the advertisement columns appears at page 534.

Naval and Military Appointments

ROYAL NAVAL MEDICAL SERVICE

Surgeon Commander N. A. H. Barlow to the *President*, for Royal Tournament.

Surgeon Lieutenant D. W. Walker to the *Furious*.

F. H. Ward has entered as Surgeon Lieutenant for short service, and is appointed to the *Victory*, for Royal Naval Hospital, Haslar.

ROYAL NAVAL VOLUNTEER RESERVE

(seconded), C. J. Hassett, S. G. O'Neill, F. J. Doherty, J. W. D. Goodall (seconded), C. B. Miller (seconded), E. Parry, and W. G. Kennedy.

Association Notices

SIR CHARLES HASTINGS CLINICAL PRIZE

The Sir Charles Hastings Clinical Prize, which consists of a certificate and a money award of fifty guineas, is again open for competition in respect of 1935. The following are the regulations governing the award:

1. The prize is established by the Council of the British Medical Association for the promotion of systematic observation, research, and record in general practice; it includes a money award of the value of fifty guineas.

2. Any member of the Association who is engaged in general practice is eligible to compete for the prize.

3. The work submitted must include personal observations and experiences collected by the candidate in general practice, and a high order of excellence will be required. If no essay entered is of sufficient merit no award will be made.

4. Essays, or whatever form the candidate desires his work to take, must be sent to the British Medical Association House, Tavistock Square, London, W.C.1, not later than December 31st, 1934.

5. No study or essay that has been published in the medical press or elsewhere will be considered eligible for the prize, and a contribution offered in one year cannot be accepted in any subsequent year unless it includes evidence of further work.

6. If any question arises in reference to the eligibility of the candidate, or the admissibility of his or her essay, the decision of the Council on any such point shall be final.

7. Each essay must be typewritten or printed, must be distinguished by a motto, and must be accompanied by a sealed envelope marked with the same motto, and enclosing the candidate's name and address.

8. The writer of the essay to whom the prize is awarded may, on the initiative of the Science Committee, be requested to prepare a paper on the subject for publication in the *British Medical Journal*, or for presentation to the appropriate Section of the Annual Meeting of the Association.

9. Inquiries relative to the prize should be addressed to the Medical Secretary.

SCHOLARSHIPS AND GRANTS IN AID OF SCIENTIFIC RESEARCH

Scholarships

The Council of the British Medical Association is prepared to receive applications for Research Scholarships as follows: an Ernest Hart Memorial Scholarship, of the value of £200 per annum, a Walter Dixon Scholarship, of the value of £200 per annum, and three Research Scholarships, each of the value of £150 per annum. These Scholarships are given to candidates whom the Science Committee of the Association recommends as qualified to undertake research in any subject (including State medicine) relating to the causation, prevention, or treatment of disease. Each Scholarship is tenable for one year, commencing on October 1st, 1934. A Scholar may be reappointed for not more than two additional terms. A Scholar is not necessarily required to devote the whole of his or her time to the work of research, but may hold a junior appointment at a university, medical school, or hospital, provided the duties of such appointment do not interfere with his or her work as a Scholar.

Grants

The Council of the British Medical Association is also prepared to receive applications for Grants for the assistance of research into the causation, treatment, or prevention of disease. Preference will be given, other things being equal, to members of the medical profession and to applicants who propose as subjects of investigation problems directly related to practical medicine.

Conditions of Award: Applications

Applications for Scholarships and Grants must be made not later than Saturday, May 12th, 1934, on the prescribed form, a copy of which will be supplied on application to the Medical Secretary of the Association, B.M.A. House, Tavistock Square, W.C.1. Applicants are required to furnish the names of three referees who are competent to speak as to their capacity for the research contemplated.

BRANCH AND DIVISION MEETINGS TO BE HELD

ABERDEEN BRANCH: CITY OF ABERDEEN AND ABERDEEN AND KINCARDINE COUNTIES DIVISIONS.—Conjoint meeting at 29, King Street, Aberdeen, Thursday, May 10th, 5.15 p.m. Election of representatives and deputy representatives. Annual Report of Council.

DEATH

- STEVENSON.—Walter Lowther Stevenson, M.B.Ed., at his residence, Church Brae, Strathane, Co. Tyrone, N.I., on March 13th, 1934.

CHEMICAL TRANSMISSION OF THE EFFECTS OF NERVE IMPULSES*

BY

SIR HENRY DALE, M.D., F.R.C.P., F.R.S.

DIRECTOR OF THE NATIONAL INSTITUTE FOR MEDICAL RESEARCH, HAMPSHIRE

INTRODUCTORY

The term "humoral transmission" was used by Otto Loewi (1921) in describing the first direct demonstration of the process which forms the subject of my lecture. There appears to have been some uncertainty as to whether the term "humoral" referred to the experimental transfer on which that demonstration was based, or to the natural process of release of a specific stimulant into the tissue fluids. In any case I shall have to consider some instances in which the chemical transmitter of nervous effects appears to be released in such immediate proximity to the receptive cells that the use of the term "humoral" would risk a misleading implication. For this reason I have chosen to employ the more general term "chemical transmission" for the process, and shall refer to the agents concerned as "chemical transmitters."

PHYSIOLOGY OF TRANSMISSION

The transmission of the effects of impulses in nerve fibres, to awaken or to modify the activity of cells in relation to which the nerve fibres end, is one of the classical problems of physiology; and the classical subject for its experimental study has been the familiar preparation of motor nerve and voluntary muscle.

Since the experiments of Claude Bernard it has been known that the point where the nerve fibre ends, on the end-plate of the muscle fibre, has special physiological properties. If the response of the muscle to a nerve impulse is paralysed by curare or by fatigue, it is here that the excitatory process is blocked, while nerve fibre and muscle fibre are still normally responsive, and still normally conduct. The fact that the transmission of excitation is peculiarly liable to interruption at this point would not by itself imply that a different process or mechanism of transmission here intervened. It might merely indicate that structures using the same process of conduction as nerve and muscle were here most readily accessible to certain poisons or to the depressant effect of fatigue. Lapique explains it as due to a change in the chronaxie of the muscle fibres. And I think that I am right in supposing that the prevalent conception of the excitation of a voluntary muscle fibre by a nervous impulse assumes that the wave of physio-chemical disturbance, propagated along the nerve fibre as the nervous impulse, passes directly to the muscle fibre, and there excites contraction as it is further propagated.

This conception of the unbroken physical transmission of the excitation wave from nerve to muscle might well seem to receive support from the analogy between the nerve-muscle junction and a synapse of the nervous system. In both cases we have the terminal branching of a nerve fibre, the axon process of a neurone, making contact with another cell—the cell body of another neurone or a muscle fibre. In the case of the synapse the response excited is a nerve impulse in the axon of the second neurone, essentially similar to that which is conducted to the synapse by the axon of the first. The suggestion of unbroken propagation is strong; and if such continuity of conduction occurs at a synapse there is no obvious reason why it should not occur at a nerve-muscle junction.

There can be no suggestion, however, that all the

events at a synapse can be described in terms of the simple conduction of an impulse. Whereas conduction is equal in either direction in nerve or muscle fibre, the excitation can pass a synapse or a nerve-muscle junction in only one direction. Sherrington and his pupils, in their great analysis of central reflex action, have considered such phenomena as recruitment, the subliminal excitatory state, after-discharge, and inhibition; and Sherrington (1925) has been led thereby to a clear recognition of something, whether a chemical substance or a state, persisting at a synapse well beyond the duration of the incident impulse. Further, with regard to the transmission of excitation from motor nerve to voluntary muscle, Adrian (1933), in a recent article, admits that it may not be so fundamentally different from that which we shall presently consider in the case of autonomic nerves, but that "an excitatory substance liberated at a nerve ending, but destroyed within a few thousandths of a second . . . would account well enough for the known properties of a nerve ending."

The direct evidence, however, for the intervention of such a chemical transmitter between nerve impulse and effector cell came, in the first instance, from studies of the nervous control of the activities of involuntary muscle and gland cells by nerves of the autonomic system. Since it is the theme of my lecture, I think it will be proper to attempt to trace the conception to its origin, and to pass in brief review the stages in the unfolding of the story. Naturally I cannot, in a lecture, attempt a comprehensive and detailed record of the evidence to which many have contributed, and I must select for mention, not necessarily those items which are more important than others, but those which seem to suit my purpose of telling a coherent story.

EARLY SUGGESTIONS OF CHEMICAL TRANSMISSION

The suggestion that nervous effects might be transmitted by the release of a specific chemical stimulant was first made in 1904 by T. R. Elliott, then working as George Henry Lewes student in the department of physiology at Cambridge. He had just worked out in detail the now familiar correspondence between the actions of adrenaline and those of true sympathetic nerves; and I myself had the pleasure of co-operating with him in a few experiments which showed that this correspondence extended to the selective action of ergotamine, which paralysed the same group of effects in the actions of adrenaline and of sympathetic nerves.

Elliott advanced, in explanation, the daring idea that sympathetic nerve fibres liberate adrenaline at their endings, to act as the transmitter and immediate agent of their effects. The years have justified his courageous insight, but I think that the late W. E. Dixon was almost alone at that time in seizing the idea with eager conviction. Dixon (1906, 1907) went further, to argue that parasympathetic nerves must similarly release a chemical transmitter of their effects. There was nothing then known in the body to play this part, and Dixon could only think of the parasympathetic transmitter as muscarine. He did, however, make an experimental attempt to find evidence of its release in the mammalian heart when the vagus nerves were stimulated. Removing a dog's heart while it was under vagus inhibition, he made, concentrated, and partially purified an extract from it; and he found that

* The Lecture Lecture of St. John's College, Cambridge, delivered on May 31, 1934, in the Department of Physiology, Cambridge.

this, when applied to the beating frog's heart, had an inhibitor effect which atropine annulled. I have a lantern slide from a record of this effect, which Professor Dixon gave to me.

FIG. 1.—Unpublished record from an experiment in 1906 by the late W. E. Dixon. Beat of the exposed heart of a frog. At the first mark extract from inhibited dog's heart applied; at the second mark atropine.

Nobody can say now what he had in his extract, though we may be pretty sure that it was not the labile substance now known to transmit vagus effects, and that its presence had little, if any, connexion with the inhibition of the heart from which it was extracted. Probably it was choline. It is beyond doubt, however, that Dixon, following Elliott's suggestion concerning adrenaline, had at that early date a conception of the general nature of the mechanism which later evidence has completely justified.

ACTIONS OF ACETYLCHOLINE

From 1906 to 1921 there is a gap in the record of direct contributions to the theory of chemical transmission. The idea was there, in the backs of many minds, but waiting for direct evidence to stimulate its further development. Mention should be made, however, of two investigations on the action of a substance which was to play a part of central importance in these developments when they came.

As long ago as 1900 Reid Hunt had begun experiments on depressor constituents of the suprarenal gland. He could not find enough choline to account for the depressor action of an extract, and he was led, in 1901, to suggest that the excess of activity might be due to an unstable and more active derivative of choline. Since the additional activity was not abolished by atropine, it now seems more probable that Hunt was dealing with histamine, the action of which was not known till much later; but he had the idea of a choline derivative, and it led him to try the action of a number of esters, which were made for him by Taveau (Hunt and Taveau, 1906). Among these was the acetic ester, acetylcholine, which Hunt found to have an action like that of choline, but about one thousand times as strong. This observation was published in the same year, and, indeed, at the same meeting of the British Medical Association as Dixon's first tentative mention of his heart-vagus experiment.

One other happening in 1906 should be noted in passing. It was then that Howell (1906, 1908) began to put forward the evidence which led him to suggest that vagus impulses inhibit the heart by mobilizing potassium ions. This is sometimes quoted as an early forecast of our present knowledge of chemical transmission, but its interest seems to me to lie in a different direction.

Some seven or eight years later, having come across acetylcholine accidentally, as a constituent of a particular sample of ergot and therefore as a product of nature, I was led to make a detailed study of its action (Dale, 1914). This, I think, gave the first hint that acetylcholine might have an interest for physiology. It was found to be a very unstable substance, even outside the body; but when it was injected into the circulation its effects, though immediate and intense, were so extraordinarily evanescent that I suggested, rightly as it now appears, that it was probably hydrolysed with great rapidity by an esterase in the blood, being split into acetic acid and the comparatively inactive choline. Then I was struck by the remarkable fidelity with which it reproduced the various effects of parasympathetic nerves, inhibitor on some organs and augmentor on others—a

fidelity which I compared to that with which adrenaline reproduces the effects of the other, true sympathetic, division of the autonomic system. Thus we now had knowledge of two substances, both with intense activities; both, by reason of their liability to the actions of different body ferments, having similarly evanescent effects; and each reproducing, with a similar fidelity, the effects of one of the two main anatomical divisions of the autonomic nervous system. There was this difference between the two cases, however, that adrenaline was already known as a natural substance, formed in and secreted from the cells of the suprarenal medulla into the blood, and thus, by its direct action from the blood stream, supplementing the effects of sympathetic nerves which it so accurately reproduces. This natural occurrence gave an added plausibility to Elliott's suggestion that adrenaline intervened in the direct effects of sympathetic nerve impulses; whereas in 1914, as I was bound to admit, we had no evidence at all that acetylcholine was a constituent of any part of the animal body, and many years, in fact, elapsed before we found it there.

There was yet another action of acetylcholine, which seemed at the time to have no relation to any physiological function. Its parasympathetic effects, produced by extremely minute doses, were all readily annulled by a small dose of atropine. Only when these had thus been suppressed was it recognized that larger, but still small, doses of acetylcholine had a stimulating action on ganglion cells, recalling that of nicotine. This is an action shown by many bases of the quaternary ammonium type, to which acetylcholine belongs. To the nicotine-like action of acetylcholine belong also its later-described stimulating effects on voluntary muscle—on normal muscles of some lower vertebrates and motor-denervated muscles of mammals (Riesser, 1921, Frank, Nothmann, and Hirsch-Kauffmann, 1922, 1923, Dale and Gasser, 1926). We shall see later that this action also has quite recently acquired a physiological significance of very great interest. For the time, however, it was only possible to recognize the fact that acetylcholine, in common with other choline esters indeed, but with a unique intensity and evanescence, exhibited these two types of action, which I referred to as its "muscarine" and "nicotine" actions.

THE EXPERIMENT OF OTTO LOEWI ON VAGUS INHIBITION

The observations recorded above were completed in the fateful year 1914, when the outbreak of war diverted all scientific energies from their normal applications. The next chapter in our story, accordingly, opened seven years later, in 1921: but it was one of outstanding importance. In that year (1921) Otto Loewi published his simple, elegant, and convincing demonstration that the vagus nerve produces its effect on the frog's heart by liberating an inhibitor substance. He showed that this substance, as obtained in the fluid filling the heart, can be transferred to another heart, and there reproduce the vagus effect.

The experiment demanded no special technique or apparatus; it might, one reflected, have been made at any time during the fifteen years or more since the idea of a specific chemical transmission of nervous effects first took shape. It needed only that touch of scientific courage which has led to the making of some of the most important discoveries by direct and simple means.

This classical experiment formed the starting-point for a series of others, in Loewi's laboratory and elsewhere, in which the liberation of a substance having properties similar to those of the vagus substance, and similarly transmitting parasympathetic effects, has been shown to accompany the reflex production of the autonomic actions of the third cranial nerve (Engelhart, 1931), and the production by artificial stimulation of the effects of the

chorda tympani on the salivary gland and the tongue (Babkin, Alley, and Stavsky, 1932), Gibbs and Szelöczy, 1932, Bain, 1932, Henderson and Roepke, 1933, and Feldberg, 1933).

RESEMBLANCE OF THE "TRANSMITTER" TO ACETYLCHOLINE

Loewi not only demonstrated the liberation of an inhibitor substance transmitting the effect of the vagus to the frog's heart; he was able, even with the minute traces obtained, to examine the properties of the substance in several directions; and these properties were found to correspond, in every test, to those of acetylcholine. Atropine annulled the action of the transmitter, but did not prevent its liberation by the vagus. The transmitter was rapidly destroyed by an esterase present in the heart muscle, and its activity could be restored by acetylating the residue. Of special interest, and of great value for further progress, was the discovery that eserine (physostigmine) inhibited the action of the esterase; so that the actions of atropine and eserine, in paralysing and intensifying respectively the action of the vagus on the heart, were fully explained by the new knowledge that this action was transmitted by something indistinguishable from acetylcholine. This effect of eserine was given a more general application, when Engelhart (1930) in Loewi's laboratory, and Matthé (1930) in my own, showed that, even in very high dilutions, it blocked the destructive action of a blood esterase on acetylcholine. We thus came to regard eserine as an indicator for the action of an unstable choline ester, like acetylcholine. Whenever eserine was found to intensify or prolong a nervous effect there was now reason to suspect that this was transmitted by the release of an unstable choline ester. To use a terminology which I recently suggested, eserine became an indicator of "cholinergic" effects.

CHEMICAL TRANSMISSION OF SYMPATHETIC EFFECTS

Before we pass to later developments concerning acetylcholine it will be convenient to deal with those in another chapter of the story, which also began with Loewi's observations.

You will remember that the vagus of the frog contains fibres which join it from the sympathetic chain, and that the effect of these sometimes predominates, so that stimulation of the mixed nerve may cause acceleration and augmentation of the heart beat, instead of inhibition. Loewi found that in such cases the fluid in the heart would transmit an accelerator, adrenaline-like effect to another heart; so that Elliott's speculation, as to the meaning of the similarity of sympathetic effects to those of adrenaline, received at last a direct experimental justification.

Further progress in our knowledge of this chemical transmitter of the peripheral effects of true sympathetic nerves has come largely from Cannon's laboratory at Harvard, and from the researches of visitors from other countries who have worked there. Cannon's recent researches have been largely concerned with the demonstration that, when the lower end of the sympathetic chain is stimulated in a cat deprived of its suprarenal glands, something passes into the blood which produces, at a distance, effects of sympathetic stimulation on other organs (Cannon and Bacq, 1931). The substance seems to be liberated largely in connexion with the pilomotor action. To avoid a premature suggestion as to its chemical nature, Cannon refers to this transmitter of sympathetic effects as "sympathin." There is an obvious probability in favour of its being the substance, natural to the body, and reproducing sympathetic effects with such remarkable precision—adrenaline itself, as suggested long ago by Elliott.

Bacq of Liège, for a time a co-worker with Cannon, has shown that when the cervical sympathetic nerve is stimulated sympathin appears in the aqueous humour of the eye (1933); just as Engelhart had found that, when the pupil was caused to constrict by the incidence of light, something like acetylcholine appeared in the same fluid. Bacq has been able to apply to the sympathin so obtained certain chemical and spectrographic tests, the results of which seem to make it clear that it is, at least, a catechol derivative with an aminated side-chain—in other words, that it is either adrenaline itself or a very closely related substance. There is a complication, due to recent observations of Cannon and Rosenbluth (1933), which suggest that sympathin, as it passes into the blood from the site of its liberation, may produce on distant organs only the augmentor, or only the inhibitor, effects of sympathetic nerves. It would be possible, indeed, to name substances closely related to adrenaline, but producing in the one case mainly the motor, and in the other case mainly the inhibitor, actions of adrenaline and sympathetic nerves; but we have no kind of warrant for regarding these as substances likely to occur naturally in the body. Cannon supposes that the actual transmitter is a substance capable of producing either type of effect, as adrenaline does, according to the type of receptive substance which it finds, and combines with, in the effector cell. He imagines that two types of such combination may occur, producing what he calls "sympathin E" and "sympathin I," which have augmentor and inhibitor effects respectively; and it is these combinations, he believes, which escape to some extent into the blood stream. It should be said, I think, that the behaviour of the substance transmitting parasympathetic effects, concerning which more is known, provides no analogy for this conception. Whether liberated by an augmentor or an inhibitor nervous effect, it behaves like acetylcholine itself, and produces on all cells which are sensitive to that substance its characteristic effects, whether inhibitor or augmentor.

We may safely leave the details of the chemical transmission of peripheral sympathetic effects to the further investigations of Cannon* and his school, and return to the transmission of the peripheral effects of parasympathetic nerves. We shall find there a mechanism which is beginning to have a much wider application than could have been suspected, even a few months ago.

ACETYLCHOLINE, A NATURAL BODY CONSTITUENT

We have seen that Loewi's vagus substance, and that liberated in the transmission of other parasympathetic effects, showed all the properties of acetylcholine, so far as these could be examined. There was a proper reluctance at first to assume identity with that substance, in default of any chemical evidence of its occurrence in the animal body. That impediment, it seems to me, was largely removed when Dudley and I (1929), looking for another substance in extracts from the spleen of the ox and the horse, came by accident on an activity like that of acetylcholine, and succeeded in isolating that substance in a quantity sufficient for clear chemical recognition. Since then Kapfhammer and his colleagues in Freiburg (Kapfhammer and Bischoff, 1930; Bischoff, Grab, and Kapfhammer, 1931) claim to have found it in much larger quantities in almost every organ of the body; but my laboratory has failed to confirm their observations. In only one other tissue, the human placenta (Chang and Gaddum, 1933), have we found evidence of the presence of acetylcholine in amounts of the same order as those occurring in the spleens of the large ungulates. Neither

* Professor Cannon's own account of the full evidence concerning this function, and of his present interpretation of it, will shortly be published in his recently delivered Kober Lecture, of which he has kindly allowed me to see the manuscript.

in the spleen nor in the placenta does its occurrence in these large amounts have any obvious relation to the action of parasympathetic nerves, or to any other known physiological function. We may reasonably hope that the meaning of its presence in such organs will some day be revealed; and, meanwhile, we may be satisfied with the evidence that acetylcholine is a normal product of the animal body, and that there is no reason, on that account, for suspecting that the choline ester transmitting parasympathetic effects is any other than this one.

DIFFICULTIES CAUSED BY SOME ACTIONS OF ATROPINE

A difficulty which some have found in accepting this identification is connected with the effects of atropine. There are some parasympathetic effects, such as the action of the vagus on the intestine, and the vaso-dilator actions of parasympathetic nerves in general, which are resistant to atropine, though the otherwise similar actions of injecting or applying acetylcholine are readily abolished by it. But, as Gaddum and I (1930) have argued in dealing with cases of this kind, the fact that such nerve effects are potentiated by eserine gives good reason for believing that they are transmitted by a sensitive choline ester; and, since these muscarine actions of all choline esters are equally liable to annulment by atropine, the resistance of the nervous actions to that alkaloid must have some other explanation. We certainly do not avoid the difficulty by talking of the transmitter as an "acetylcholine-like substance." If the atropine anomaly were sufficient to exclude the identification of the transmitter as acetylcholine, it could not be a choline ester at all, as the action of eserine shows it to be. Gaddum and I suggested that in such cases the nerve impulses liberate acetylcholine so close to the reactive structures that atropine cannot intervene, whereas it can prevent its access to them when it is artificially applied from without.

PHYSIOLOGICAL RECOGNITION OF ACETYLCHOLINE

To settle the matter beyond discussion we should presumably need to collect a sufficient quantity of the substance transmitting the effects of nerve impulses to enable it to be chemically identified. Perhaps some day we may be able to do this, but there is no immediate prospect of its achievement.

In default of this possibility there are various tests we can apply, the cumulative effect of which is to make the identification practically certain. It can be shown that the transmitter is a very unstable choline ester, rapidly destroyed at a definitely alkaline reaction, even at room temperature; that it is rapidly destroyed by the esterase present in blood, which the Stedmans have shown to be an enzyme specific for esters of choline, but that it is protected from this enzyme by a small proportion of eserine. We can then determine its activity in terms of acetylcholine by a number of different physiological tests—by its vaso-dilator depressor action in the rabbit or cat, its inhibitor action on the isolated frog's heart or rabbit's auricle, its stimulation of contracture in the frog's voluntary muscle, or the body wall of the leech sensitized to it by eserine. This reaction of leech muscle, recently brought to my laboratory from Germany by Dr. Feldberg, is of amazing sensitiveness, and of special value for detecting and measuring acetylcholine in blood. And when it is found that, in all these different reactions, the activity of a solution containing the parasympathetic transmitter is matched by the same strength of acetylcholine, we can be practically certain that we are dealing with that substance and with no other choline ester. And since it is the only choline ester known to occur in the body at all there seems no reason to look further. Feldberg and I (Dale and Feldberg, 1933) have been able, for example, to collect the substance released in the wall

of the dog's stomach when the vagus nerves are stimulated, and have found it to correspond exactly with acetylcholine in all these different respects. We suggest that the mode of transmission of vagus impulses is not likely to change abruptly on passing from stomach to intestine. It seems to be very much more probable that the actions of the vagus on the small intestine, and of the pelvic nerve on the large intestine, are similarly transmitted by the release of acetylcholine, but in such proximity to the reactive structures that atropine interferes but little with its action. This, however, is a point on which direct evidence has yet to be obtained.

CLASSIFICATION BY CHEMICAL FUNCTION. CHOLINERGIC AND ADRENERGIC NERVES

In general, it holds good that acetylcholine, or some choline ester indistinguishable from it, is the chemical transmitter of peripheral parasympathetic effects, while that for the actions of true sympathetic nerves is either adrenaline or some closely related substance. To this broad correspondence, however, between chemical function and anatomical origin, there are exceptions. It seemed to me that we needed words to indicate the functions of nerve fibres as regards the chemical transmission of their activity, without reference to their anatomical connexions, and I have proposed the use of the adjectives "cholinergic" and "adrenergic" in this sense (Dale, 1933).

The most obvious exceptions to the general correspondence are those of nerve fibres which arise from sympathetic ganglion cells, but are cholinergic. Langley (1901) and Elliott (1905) found it impossible to detect a stimulation by adrenaline of sweat glands in the cat's foot or the human hand, corresponding to the effect on them of sympathetic nerve impulses. The sweat glands of the cat, indeed, have long presented a puzzle and an anomaly to the systematic pharmacologist; for they respond but little to adrenaline, but they are stimulated to profuse secretion by substances like pilocarpine and acetylcholine, and their activity is readily paralysed by atropine and unaffected by ergotoxine, though their nerves belong to the true sympathetic system. The anomaly would obviously be explained if these particular sympathetic fibres were cholinergic, and not adrenergic like most.

Quite recently Feldberg and I have obtained direct evidence that this is the case.

We perfused the foot of a cat, the hairless pads of which carry the sweat glands, with Locke's solution containing a little eserine. As soon as we stimulated the sympathetic nerve supply to the foot and caused sweating on the pads, acetylcholine appeared promptly in the venous fluid. It disappeared when the glands returned to rest and reappeared on renewing the stimulation; but it did not appear at all, though the stimulation was still effective on the blood vessels of the foot, if the hairless pads, with their sweat glands, were excluded from the perfusion.

We cannot perform an experiment of this kind on man, but the cholinergic nature of the nerve supply to the human sweat glands is clearly indicated by their failure to respond to adrenaline, their response to pilocarpine

FIG. 2.—Isolated leech muscle treated with eserine, tested with effluents from perfused cat's foot. C_1 and C_2 = control fluids without stimulation. S_1 = fluid during sympathetic stimulation, from foot with sweat glands excluded from perfusion. S_2 = fluid during exactly similar stimulation, from foot with sweat glands included in perfusion.

with profuse secretion, and their paralysis by atropine. In some other animals, however, the nerve supply to the sweat glands appears to be adrenergic—for example, in the horse.

Another effect of sympathetic nerve stimulation which is not reproduced by adrenaline is the vaso-dilatation in the buccal mucosa in the dog, long ago described by Dastre and Morat (1880) as caused by stimulating the cervical sympathetic nerve in that animal. Rogowicz (1885) showed that when the voluntary muscles of the dog's cheek were denervated they responded with contraction when the cervical sympathetic nerve was stimulated. This was closely similar to the effects which we (Dale and Gaddum, 1930) elsewhere attributed to the leak on to the sensitized muscle fibres of acetylcholine, released to transmit a vaso-dilator effect; and Euler and Gaddum (1931), who reinvestigated this Rogowicz phenomenon, concluded that it was, indeed, due to the presence in the dog's cervical sympathetic nerve of fibres which were truly sympathetic, but acted by release of acetylcholine—being what we should now call cholinergic sympathetic fibres.

A study of the similar contracture of the muscles of the hind limb deprived of their motor nerves, originally described by Sherrington, led Gaddum and me (1930) to the conclusion that the antidromic vaso-dilatation, produced by impulses in side branches of sensory nerve fibres to the small arteries, was also cholinergic. More recent evidence by Hinsey and Cutting (1933) suggests that the Sherrington phenomenon is due to sympathetic cholinergic fibres joining the sciatic plexus through the grey rami, and not, as had been thought, to antidromic impulses in sensory fibres. The question, whether the axon-reflex or antidromic vaso-dilatation is cholinergic, is therefore once more open, and will require direct evidence for its decision.

NICOTINE ACTIONS OF ACETYLCHOLINE

Mention of the pseudomotor phenomena leads us to the other aspect of the action of acetylcholine—what I have termed its "nicotine" action—the physiological interest of which has only very recently begun to appear. This was a question which had puzzled me for many years. Why should Nature use, as the transmitter of parasympathetic effects to involuntary muscle and gland cells, such a substance as acetylcholine, having not only the action directly appropriate to this purpose, but, in addition, a "nicotine" action on ganglion cells and voluntary muscle which seemed entirely irrelevant to it?

The ruling conceptions of the mode of transmission of nerve impulses across synapses to ganglion cells, or from motor nerve endings to the end-plates of voluntary muscle fibres, made it difficult to speculate on any intervention of acetylcholine in such cases. Only in the past few months have the experimental facts demanded a serious consideration of such a possibility. Some years ago Witanowski (1925) detected the presence of something like acetylcholine in extracts of sympathetic ganglia, and Chang and Gaddum (1933) came across it again, using tests which gave clearer evidence of its identity. In both cases it was found also in the cell-free nerve, and the significance of the observations was not clear. Kibjakow (1933), however, published a description of experiments in which he had artificially perfused the superior cervical ganglion of a cat, and found that, when the preganglionic nerve was stimulated, something appeared in the venous fluid which acted as a stimulus to the ganglion cells on reinjection, as shown by the contraction of the nictitating membrane. He suggested that the impulses were transmitted across the synapse by the release of this substance, and Chang and Gaddum, in the light of their own observations, suggested that Kibjakow's substance might be acetylcholine.

TRANSMISSION OF NERVE IMPULSES TO THE ADRENAL MEDULLA

An encouragement to the further consideration of this possibility, and to its ultimate testing by experiment, was furnished by Feldberg and Minz's (1933) discovery that, when the splanchnic nerve supply to the suprarenal medulla is stimulated, acetylcholine appears in the blood of the suprarenal vein, if its destruction is prevented by eserine; so that acetylcholine here transmits, to the medullary cells, the nerve impulses which cause them to secrete adrenaline into the blood. Now the suprarenal medullary cells are morphologically equivalent to sympathetic ganglion cells, and at least some sympathetic preganglionic fibres appear to end in direct relationship to them. Further experiments, which Feldberg has now completed in my laboratory, have shown that, in harmony with this conception, it is chiefly the nicotine action of acetylcholine which is concerned in its action on these medullary cells, and in the transmission to them of the effects of splanchnic impulses.

TRANSMISSION OF IMPULSES AT GANGLIONIC SYNAPSES

With this analogy before them, Feldberg and Gaddum (1933) have proceeded to a direct test of the possibility that the transmission of a nerve impulse across the synapse in a ganglion is effected by the release of acetylcholine. They have used Kibjakow's technique for perfusing the superior cervical ganglion, recording contractions of the nictitating membrane as an index of the activity of the ganglion cells. They obtained no result when plain Locke's solution was used, but when a very low concentration of eserine was added to it an active substance appeared in the venous fluid whenever the preganglionic nerve was stimulated, but only then. And this substance, by all the tests with which we are now familiar, corresponds so exactly in its properties and actions to acetylcholine that there is no reason to doubt its identity.

The conception of the transmission of a nervous impulse across a synapse by the release of such a substance, and by the action of this substance as the direct stimulant of the ganglion cell, though it satisfies my own desire to bring the nicotine action of acetylcholine into the physiological picture, is not without its difficulties, and it will have to justify itself to win general acceptance. One thing is clear—namely, that when preganglionic impulses arrive in the ganglion acetylcholine is there released in such an amount that it not only may but *must* stimulate the ganglion cells to their only known form of activity, in the output of impulses in the post-ganglionic fibres, corresponding to those which arrive in the preganglionic fibres.

Several recent investigations (Bishop and Heinbecker, 1932, Brown, 1934, and Eccles, 1934) have shown that a single impulse in a preganglionic fibre produces a corresponding single impulse in post-ganglionic fibres, and that the delay at the synapse is very short. One can only suppose that each impulse must cause the release, in immediate proximity to the ganglion cell, of a minute charge of acetylcholine, which fires off a post-ganglionic impulse and then immediately disappears. At this early stage we must wait for the additional evidence, which is almost daily accumulating in my laboratory; and I can only say that it seems to be wholly in favour of some such conception.

TRANSMISSION OF NERVOUS EXCITATION TO VOLUNTARY MUSCLE

Finally we are led, by the analogy which I mentioned at the beginning of my lecture, to inquire whether acetylcholine may not intervene, also by virtue of its nicotine

action, in the transmission of the effect of a motor nerve impulse to a voluntary muscle fibre. For a good many years there have been indirect indications of such a possibility. If we extend our view to a wider range of animal types, the demarcation between the functions and the modes of innervation of striated muscle on the one hand, and of plain muscle on the other, is not everywhere so sharp as we are apt to regard it in dealing with the mammal. The intestine of the tench, a common fresh-water fish, has two muscle coats—one striated, the other plain—and both are innervated by fibres from the vagus. Acetylcholine stimulates the former to a relatively rapid and short contraction, the latter to a prolonged increase of tone and rhythm; and its effect on the striated coat is of the nicotine type, being paralysed by curare, while that on the unstriated coat is of the muscarine type, being paralysed by atropine (Mehes and Wolsky, 1932).

FIG. 3.—Isolated intestine of *Tinca vulgaris*. Acetylcholine (1 in 50,000) added at mark, producing quick contraction of striated muscle coat and slow contraction, with rhythm, of unstriated coat. (Reproduced from Mehes and Wolsky, *Arch. d. Ungar. Biol. Forsch.*, vol. v, p. 150.)

The dual activities of acetylcholine, and the corresponding paralytic effects on them of atropine and curare, are similarly plain when we compare its actions on the unstriated sphincter of the mammalian pupil, and on that of the bird, which consists of striated fibres. The fact that acetylcholine stimulates certain normal voluntary skeletal muscles in lower vertebrates, and those of mammals after degeneration of their motor nerves, I have already mentioned.

There has been evidence, from several observers, of the appearance of something like acetylcholine in the venous effluent from a perfused voluntary muscle when its nerve is stimulated (Hess, 1923, Shimidzu, 1926, Brinkman, 1924, 1925, and Plattner, 1932). In all these cases, however, the nerve stimulated was a mixed nerve, containing sensory and sympathetic fibres as well as voluntary motor fibres, and the evidence did not clearly suggest, even to its authors, that the appearance of

acetylcholine was connected with the transmission of voluntary motor impulses. The idea involved the same kind of difficulties as that of its action as transmitter at ganglionic synapses. With the direct evidence now before us with regard to transmission in a ganglion, it seemed that an effort must be made to get a clearer test of the possibility of its acting similarly in the case of motor nerve and voluntary muscle.

The few experiments which Feldberg and I have as yet completed have given results

FIG. 4.—Isolated leech muscle (eserine) tested with fluids from perfused cat's tongue. C = without stimulation; S = during rhythmic stimulation of hypoglossal nerve; S (alk.) = same fluid as S, but made alkaline and kept at room temperature for an hour.

which seem to be so definitely favourable to such a conception as to justify reference to them even at this early stage.

The hypoglossal nerve carries purely motor fibres to the voluntary muscle of the tongue, mixed only with sympathetic fibres, which can be caused to degenerate by removing the superior cervical ganglion. If the tongue of a cat is perfused with Locke's solution containing a small amount of eserine, and is made to contract by stimulating this purely motor nerve supply, acetylcholine appears in the outflowing solution while the stimulation is continued, disappears during a follow-

ing period of rest, and reappears when effective stimulation is resumed.*

The observations are too new and too incomplete for detailed analysis of their meaning. We must bear in mind the fact that the responses of skeletal muscles, whether normal or denervated, to the artificial application of acetylcholine, either to the surface of the isolated muscle or through the circulation, take the form of relatively slow and weak contractions, and not of twitches. There is, indeed, no reason to expect that, when reaching successive muscle fibres by diffusion from the surface or from the blood vessels, acetylcholine would produce effects of the same type as those which might result from its sudden and simultaneous release in immediate proximity to the end-plates of all the fibres of the muscle, and its equally sudden removal, after the manner of the "excitatory substance" admitted by Adrian as a possibility. It might be suggested, however, that acetylcholine, even if thus liberated by motor nerve impulses, would probably be concerned with contractions rather than with normal twitches, and perhaps with the function of special, slow-contracting fibres. It must be admitted that these are still possibilities; but the apparent function of

FIG. 5.—Diagram of peripheral nervous system. At points marked C there is evidence of a cholinergic transmission, at those marked A of an adrenergic transmission. Doubtful cases marked ?.

acetylcholine in transmitting the effects of impulses to nerve cells encourages one to expect a more general function for it in the transmission of motor nerve impulses to voluntary muscle. In any case, the evidence, even so far as it has been obtained, seems to give promise that we may soon be able to complete the picture of the transfer of excitation, at all cytoneural junctions in connexion with the peripheral nervous system, by the liberation of chemical transmitters.

One further question is almost inevitable. Is this conception to be limited to the peripheral nervous system, or are we to expect its extension to the synapses of the central grey matter itself? With no direct experience of central nervous physiology, I cannot properly allow myself merely to speculate. Sherrington, you will recall, with his unique authority, has envisaged the general possibility of a chemical mechanism at central synapses. And it should be mentioned that Dikshit (1934), an Indian pharmacologist working in Professor A. J. Clark's laboratory in Edinburgh, has very recently shown that minute quantities of acetylcholine, if injected into the fluid of the cerebral ventricles, reproduce with a striking fidelity the

* An entirely similar result has, even more recently, been obtained with the muscles of the leg, excited to contraction by stimulating the ventral spinal roots, after extirpation of the lumbar sympathetic chain.

effects of central stimulation of the vagus on respiratory activity; and he suggests liberation of this substance in the centres by sensory impulses in the vagus.

CONCLUSION

I can best summarize the account which I have given, of research on the chemical mechanisms for the transmission of nervous stimuli and of its most recent extensions, by putting before you a rough diagram of peripheral synapses and endings of efferent nerves. In each case, where the evidence seems fairly clear, I have indicated a cholinergic mechanism of transmission by the letter C, an adrenergic mechanism by the letter A. (Fig. 5.)

You will see at once that the C's greatly preponderate, just as the later section of my lecture has dealt exclusively with acetylcholine. We get an impression of the cholinergic mechanism as having the more general application in the functions of the nervous system, and probably an earlier origin in evolution, and of the adrenergic mechanism as a more specialized and probably a more recent development. I believe that such a conception would have been congenial to the thought of one of the greatest of British physiologists, and one of the founders of the Cambridge school, the late W. H. Gaskell. You will see that in some places the diagram has notes of interrogation, representing points at which further evidence is required to justify a definite statement. There might have been many more, for the whole field of inquiry is full of unknown details, asking for investigation, and attractive to scientific curiosity. I have tried to show you the main outlines of the map, as they are now beginning to emerge.

DISEASE AT ITS ONSET

WITH SPECIAL REFERENCE TO OCULAR
MANIFESTATIONS

BY

A. MAITLAND RAMSAY, M.D., LL.D.

FELLOW OF THE ROYAL FACULTY OF PHYSICIANS AND SURGEONS,
GLASGOW; CONSULTING OPHTHALMIC SURGEON, GLASGOW
ROYAL INFIRMARY AND OPHTHALMIC INSTITUTION

Biophysics and biochemistry have taught us that the living body is an admirably equipped laboratory in which Nature is 'continually performing experiments.' These experiments resemble those conducted in every physiological laboratory in so far that some succeed while others fail. When Nature's experiments are successful we are not conscious that anything is happening; everything goes like clockwork, and we feel in good health. When, on the other hand, the experiments fail we become aware of unpleasant sensations, which we have learned to recognize as symptoms of disease. Health, therefore, must be regarded as a dynamic rather than as a passive state. We keep healthy as a result of a perpetual struggle to maintain physiological equilibrium in the reactions constantly taking place between the cells of the body and their nutrient capillaries. Physico-chemical changes, therefore, which originate in the capillary system are, in all probability, the first departure from health, and the cause of the earliest symptoms of disease.

The part played by the capillaries is quite distinct from that played by the heart and other blood vessels. All metabolic changes take place through their walls; consequently they form the most active, purposive, and dynamic part of the vascular system. Their contractility is controlled not only by vasomotor nerves but also by chemical stimuli, the former acting as a coarse and the latter as a fine adjustment. Krogh² has demonstrated that the capillaries are not simply tubes through which blood flows. They do not respond passively to the amplitude of the pulse wave in the arteries. They are really a constituent part of the tissues in which they lie, and their blood circulation is regulated and controlled by the requirements of the individual cells of the structures they supply. All the important business of life is transacted through the walls of the capillaries.

Bryson³ has suggested that in every part of the body the functioning unit and its associated capillaries constitute an organ in miniature. That is a simple, but it is also a most useful, conception. It implies that the health of every organ depends upon the quality and the quantity of the blood circulating in its capillary system. It is to be remembered, however, that in normal circumstances all the capillaries of an organ are not in action at the same time. They work in shifts: while some are open and active, others are closed down and idle. Herring⁴ calls this "the law of fluctuation," and points out that in all living structures the alternation of periods of activity with periods of rest is essential to health.

CIRCULATION IN THE EYE

In the eye, with the help of the ophthalmoscope, a complete circulation—arteries, veins, and capillaries—is exposed to view, and can be studied as an integrated whole, with a completeness quite impossible in any other part of the living body. Thanks to the transparency of the normal retina we can see the blood in the central artery, and can follow it into the finest arterioles and, if we make use of Friedenwald's⁵ yellow-green light, we can trace the capillary network in wonderful detail.

From the clinical standpoint the retina, although it is such a very complicated structure, can be conveniently

divided into (1) the conducting portion, and (2) the very highly specialized functioning unit. The former, comprising the ganglion cells and the nerve fibres, receives its capillary supply through the superficial and deep plexuses of the central artery, while the latter, although itself avascular, receives abundant nourishment by transfusion from the choriocapillaris. Both the central artery and the uveal blood vessels, therefore, contribute to supply the retina; and although the capillary supply of the conducting system and that of the functioning unit is distinct anatomically, yet it is strictly comparable physiologically.

In a general sense it may be said that the walls of the capillaries, although freely permeable to crystalloids, water, and gases, are relatively impermeable to colloids. The degree of permeability to colloids varies in different parts of the body, depending upon the special requirements of each particular organ. In every instance there is a biological adaptation of structure to function, and Duke-Elder⁴ has pointed out that in the eye perfect transparency is secured by almost complete impermeability of the intraocular capillaries to colloidal substances. By that means every structure peculiar to the organ of vision is kept optically homogeneous.

Visual function is wholly dependent upon the rate of the circulation of the blood in the capillaries of the retina and in the choriocapillaris; but the retinal circulation must always be considered in its relation to the general circulation. The same principles are observed in the circulation of the blood in the eye as in any other organ of the body; but the intraocular circulation is peculiar in so far as it is modified by the intraocular pressure. The capillary pressure in the eye is higher proportionately than in any other organ of the body in a state of rest, but it is neither a constant nor a measurable quantity. It varies not only in different individuals, but also in the same individual from time to time. It is, however, essential for the health of the eye that an accurate balance be maintained between the capillary pressure and the pressure of the intraocular fluids, because, as Duke-Elder has demonstrated, the intraocular fluids are a dialysate from the capillaries.

TRANSPARENCY OF THE RETINA: AN INDICATION OF HEALTH.

The capillaries are very susceptible to every morbid influence, consequently they are peculiarly sensitive to the quality of the blood. Every form of toxæmia causes rapid dilatation, with increased permeability of their walls. It is easy to understand, therefore, how the transparency of the retina becomes impaired by congestion of its capillaries, together with its infiltration with colloidal substances. This abnormal condition of the retina is recognized clinically by a want of translucency in the ophthalmoscopic picture. Here, then, we have a sign of abnormality which is as nearly as possible on the borderland between health and disease. Mackenzie always insisted that the first symptom of disease is a complaint of an unusual sensation, and an additional interest is given to the study of such sensations whenever we can discover an objective cause capable of explaining their occurrence.

We have seen from what has been said (1) that the transparency of the normal retina is due to the impermeability of the walls of the capillaries to the passage of colloidal substances, and (2) that this normal transparency is interfered with by any form of toxæmia, which causes rapid dilatation of the capillaries with increased permeability of their walls. Translucency is the most delicate quality of the ophthalmoscopic picture, and it is reason-

able to assume that any deterioration or loss of this pristine brilliancy is one of the first signs of a departure from health.

In a group of cases I have in mind the only outstanding ocular objective feature is a deepening of the colour and a lack of the normal translucency of the ophthalmoscopic picture. These subtle changes in colour and translucency are somewhat difficult to describe, but they are easily recognized after attention has been directed to them. It is only through physiology that we can approach pathology successfully from the clinician's standpoint; consequently, in dealing with a structure so delicate and sensitive as the retina, its special physiological attributes must be kept in mind. When examining a patient, therefore, in addition to testing his form sense, attention must be given to his appreciation of light and colour.

As a rule, the patients under consideration have little difficulty in reading the test types, but they often say that the letters in the middle of a line are recognized with more conscious effort than those at either end. The symptoms are not relieved by correcting any error of refraction that may be present, for the patients still complain that the eyes feel hot and uncomfortable, and are easily tired. If they persist in reading after the onset of these symptoms they are prone to suffer from a dull neuralgic pain, which radiates from the eye to the forehead and the temple. The print becomes unsteady, and a flicker makes it difficult to read, and more especially to pass easily from one line to the next. Sometimes these symptoms are accompanied by black spots in front of the eyes, by minute flashing lights scintillating in the field of vision, and by occasional sudden attacks of obscuration of sight. The light sense is nearly always disturbed. The patients have difficulty in adapting themselves to changes in the surrounding illumination. They find that their eyes are either easily dazzled by a light, which formerly they could look at without discomfort, or that they now require a much brighter light to enable them to see to work with comfort. These differences in light perception may not be easily measured and charted, but an intelligent and observant patient, assisted by a few well-directed questions, can always give a convincing description of the symptoms.

Slight disorders of the colour sense are even more difficult to detect during an ordinary clinical examination, but careful attention to the patient's description of the difficulties he is having with his sight will usually give a clue to the direction further examination should follow. For example, if a woman is in the habit of working with colours, she is likely to complain of the difficulty she now has in differentiating between varying shades of the same colour. In the group of cases we are specially considering blue is the colour which causes most difficulty. The association of a disordered colour sense for blue with a diminished light minimum at once directs attention to the functioning unit of the retina and to its capillary supply as the sites of origin of the symptoms of which the patient is complaining.

In man the blood supply both to the eye and to the brain comes from the internal carotid artery, and the retinal circulation holds many analogies with the cerebral. As similar tissues behave alike in whatever part of the body they are found, it is reasonable to assume that what can be seen in the eye occurs also, though hidden from view, in the brain. It is not surprising, therefore, that many of the patients complain of nervous symptoms, which are strictly on a par with their visual troubles. Among these may be mentioned want of the power of concentration, and unusual difficulty in remembering what they have just been reading. Many complain that in conversation they are apt to lose the thread of an argu-

ment, and come to a dead stop by forgetting what they meant to say. They are nearly always restless, irritable, impatient, forgetful, depressed, and difficult to live with. The more thoughtful among them are very apt to exaggerate the importance of these symptoms, and to become neurasthenic and hypochondriacal. It is a great help to them when they can be made to understand that both their nervous symptoms and their visual troubles are due to a similar cause, and that both of them are curable.

CAPILLARY CONGESTION IN RETINA AND DISORDERED METABOLISM

Ever since the introduction of the ophthalmoscope there has been recognized to be a close clinical relation between the eye and the kidney. In the one organ as in the other congestion of the capillaries causes impairment of function—diminished light sense in the eye, diminished output of urine in the kidney. One of the characteristic clinical features of the group of cases we are considering is interference with the full activity of the kidney. There is usually not only a diminution in the quantity of urine excreted in twenty-four hours, but also a disturbance in the normal ratio between output and specific gravity. Although the quantity of urine passed in twenty-four hours is considerably reduced, the specific gravity is not increased and is often below normal. A further evidence of an error of metabolism is usually found when a specimen has stood in a urine glass overnight, inasmuch as microscopical examination of the sediment reveals urates, or crystals of uric acid or of oxalate of lime: most characteristic of all is when the field of the microscope shows a very large number of minute oxalate of lime crystals. The frequent clinical association of a defective colour sense for blue with persistent oxaluria strongly suggests that both symptoms are the result of disordered metabolism. In the absence of any complications there is no interference with the normal excretion of urea, and neither sugar nor albumin is likely to be present.

BACTERIAL INFECTION AND THE OPHTHALMOSCOPIC PICTURE

Duke-Elder, in writing of the relation of toxæmia to high blood pressure, says: "A raised blood pressure is an expression of the effect of toxic influences acting over the whole extent of the arterio-capillary bed." Pines¹ is right, therefore, when he insists on the use of the sphygmomanometer in association with the ophthalmoscope. In the group of cases we are now considering blood pressure is almost invariably above normal, but hæmorrhage from the retinal blood vessels is exceedingly rare. It is now generally admitted that high blood pressure *per se* will not cause rupture, unless there is fragility of the walls of the vessels as a result of previous disease. Persistent hypertension is, however, in all probability a decisive factor in differential diagnosis in its relation to aetiology, prognosis, and treatment. For example, it is well known that capillary congestion of the retina can arise as a result of bacterial infection, and that it is indistinguishable by the use of the ophthalmoscope alone from a similar condition due to metabolic disorder. For obvious reasons it is very important to be able to distinguish the one condition from the other; but any evidence in my possession only warrants me in offering the suggestion that in capillary congestion of the retina search should always be made for a hidden focus of microbic infection in every case in which blood pressure shows little deviation from normal, and when an examination of the urine reveals no evidence of metabolic disturbance. The following case is a good example.

In September, 1928, a man aged 53 began to complain of discomfort in his eyes after reading. He was almost emmetropic, and the spectacles he was using for close work were quite suitable. Nothing was revealed in the examination of the eyes except marked loss of translucency in the ophthalmoscopic picture. It was thought that an error of metabolism was the cause of the symptoms, but the patient did not respond to eliminant treatment. His family doctor reported that he had always found blood pressure and urine to be normal, and that repeated examination had failed to reveal any definite disease. Although the patient never felt well, he was able to attend to his business. No one thought there was anything seriously the matter with him until May 19th, 1930, when he was seized with acute appendicitis. The condition revealed at the operation showed that the local disease must have been present for a very considerable time. Peritonitis and paralysis of the bowel followed, and the patient died within three days after the acute appendicitis had been diagnosed.

Reconsidering this case in the light of the fatal termination I feel very strongly that more attention should have been paid to the fact that urine and blood pressure were persistently normal. Had the significance of that fact been fully appreciated, it is very probable that less attention would have been given to errors of metabolism, and a more diligent search would have been made for a hidden focus of bacterial infection. In medicine intelligent search very often leads to discovery.

In none of these cases is a cure possible until the error of metabolism has been corrected, or until the source of local sepsis has been removed. So long as the exciting cause continues to operate no form of treatment will be effective. When, however, the cause has been removed capillary congestion disappears from the retina, the fundus oculi regains its normal translucency, and the patient is relieved of his general, as well as of his ocular symptoms.

Garrod² has pointed out that injurious influences proceeding from the patient's environment may so disorder normal metabolism as to cause trouble. He also says that the external factor does not affect all alike, but that it discriminates between the different members of the same family. In his clinical investigations into the part played by the home surroundings upon the health of the children, Rowand³ has found evidence in support of Garrod's research work, and has drawn special attention to a group from 2 to 6 years, all the members of which suffered from slight albuminuria. In almost every one of these children the fundus oculi, owing to loss of translucency, resembled red velvet. The optic disk was well defined in outline, but was of a rose-pink colour as a result of capillary congestion, which was observed to vary in degree from time to time in the same patient. The retinal veins were prominent and somewhat rough in outline, and the light reflex from the walls of the arteries was unusually brilliant. Both eyes were affected equally, consequently the presumption is that capillary congestion was general rather than local, and that the albuminuria was due to dilatation of the capillaries of the kidney, with increased permeability of their walls to colloidal substances, rather than to any definite renal disease. The condition of the retina, therefore, was not due to the state of the kidney, but both in the retina and in the kidney the congested capillaries were the result of general toxæmia, due in all probability to disordered metabolism, and the onset of albuminuria may be regarded as a measure of its severity. In all the children included in this group the glow of health soon returned to the face after careful dieting accompanied, when necessary, with an ample supply of vitamins A and D, with suitable tonics containing iron, and by the free use of eliminants. As soon as the toxins were removed from the blood the muddy complexion cleared, the fundus oculi recovered its normal brilliancy, and the albumin disappeared from the urine. Rowand

has been able to follow up a considerable number of these children, and he reports that all those he has been able to examine have remained in good health.

In conclusion, let me repeat that in all probability the earliest sign of disease is distension and increased permeability of the walls of the capillaries; that this may be recognized clinically by lack of translucency of the ophthalmoscopic picture; that what can be seen in the eye is an index of what is occurring in other parts of the body where the phenomena are hidden from view; and that by means of the ophthalmoscope it is sometimes possible to recognize disease in its earliest stages—that is, at a time when in all likelihood it is easily curable.

AVERTIN NARCOSIS IN OPERATIONS FOR TOXIC GOITRE

BY

GEOFFREY KEYNES, M.D.CAMB., F.R.C.S.ENG.

ASSISTANT SURGEON, ST. BARTHOLOMEW'S HOSPITAL; CONSULTING
SURGEON, L.C.C. THYROID CLINIC, NEW END

The operation of partial, or "subtotal," thyroidectomy for toxic goitre is potentially a highly dangerous procedure, and the reasons for this element of danger are plain to see. Many of the patients submitted to operation are acutely ill, and removal of part of the thyroid gland is sometimes undertaken as an emergency or life-saving measure. Even when the patient is not so ill as this, she is often existing on the edge of a precipice, and any disturbance, even of moderate severity, may be enough to push her over, either by the production of "thyroid crisis" or by putting just too much strain on an already overburdened and damaged heart. The degree of strain produced by the operation is bound to be considerable if it is completed in one stage, since it entails a wide dissection of the neck and "dislocation" of the thyroid gland, a sinister-sounding term, which seems to imply some violence. But although the potential danger of the operation is great, the actual danger seems to have been reduced in some hands to an almost negligible amount if figures of operative mortality are to be taken as a reliable indication. It is the purpose of this article to examine briefly the factors responsible for this remarkable change brought about in what was formerly regarded as an exceedingly dangerous procedure, and to support my own belief that the choice of anaesthetic has great importance. It will be illustrated from a consecutive series of 243 operations performed during the last four years on 220 patients.

FACTORS DIMINISHING OPERATIVE RISK

It would be platitudinous at the present time to enlarge upon the improvement wrought in recent years by the use of iodine in preoperative medication. It is well known that a large part of the reduction of the operative mortality has been due to this, and that iodine has its chief value in the preoperative stage, the initial improvement not being maintained if the use of iodine be prolonged. It would be difficult, also, to exaggerate the importance of improvement in the technical skill and in

the judgement of the operator. Thyroidectomy is technically one of the most exacting of operations; and one in which any failure in detail may cost the patient's life. Gentleness and precision, control of haemorrhage, and avoidance of unnecessary delay are all of importance to the patient's safety. It is notorious that the larger the number of thyroid operations in any one clinic the safer are the patients, since frequent practice makes for the establishment of an efficient routine on the part of the team and for the necessary familiarity with operative details on the part of the surgeon. This applies, in some degree, to the performance of all operations, but it is of superlative importance in the performance of partial thyroidectomy for toxic goitre.

Of great importance also is the judgement of the collaborating physician and surgeon as to when the right moment for operation has arrived, and which patients are actually so ill that any operation means certain death—nowadays a vanishing proportion of the whole. Important also is the judgement of the surgeon as to which patients should be treated by operation in two or more stages. Here, again, experience is an important factor, for which there can be no substitute.

It is clearly difficult to disentangle the relative importance of these different factors in the clinical and operative complex. One more remains, however, which I wish to consider in detail, and that is the choice of anaesthetic. A great variety of anaesthetic methods have been used, from the "thyroid-staling" method of Crile under hypnotic suggestion to the somewhat complicated method presently to be described. Ten years ago ordinary ether anaesthesia was regarded as satisfactory for operations on toxic goitre, though it was found that the inevitable disturbance to the patient from post-anaesthetic coughing and vomiting was distressing, if not directly prejudicial to her prospects; and it may be taken as a rule in dealing with toxic goitre that all disturbance reacts unfavourably on the patient, and is therefore indirectly prejudicial. An effort was accordingly made to eliminate ether anaesthesia, and a phase followed in some clinics of using local analgesia aided only by a preliminary injection of morphine and hyoscine. It was thought necessary to reinforce the effect of the narcotics by elaborate precautions directed towards the removal of external stimuli, such as noise and light—and very difficult it was to do this effectively in a busy hospital ward. The efficacy of morphine and hyoscine, too, is very variable; sometimes these drugs fail to produce adequate narcosis, and occasionally the patient becomes actually excited, the drugs having only produced loss of control without depressing the main centres of consciousness. The use of local analgesia was found to give improved results compared with ether anaesthesia, and its use was continued for some years. The injection technique which I employed was that learnt from Sir Thomas Dunhill, and consisted of local infiltration of the field of operation with 0.5 per cent. novocain solution in normal saline with 1 in 500,000 adrenaline hypochloride. Usually only about 150 c.cm. were used, so that the total amount of novocain injected amounted to 0.75 gram. A field-block of the cervical nerves was added for a short series of patients, but the analgesia appeared to be equally good without it, and it was soon abandoned as superfluous. Considering that the toxic goitre patient would seem, by the nature of her disease, to be pre-eminently unsuited for any operation under local analgesia, the results were remarkably good. Many patients, however, left the operating table with high pulse rates, and the operation entailed a great strain on both patient and surgeon. Any thyroid operation is already sufficiently exacting for the surgeon without the necessity for watching closely the patient's mental reaction throughout the procedure, and for the

patient it could only be described as an ordeal. The elimination of these objectionable features had already been attempted by various operators with the use of a rectal anaesthetic or narcotic such as ether or paraldehyde. I had myself used the former, but rejected it as being unsafe and as upsetting the patient almost as much as an inhalation ether administration. I therefore welcomed the introduction of rectal avertin when I found that it was regarded by the anaesthetists, represented by my colleagues Dr. C. L. Hewer and Dr. Frankis Evans, as a safe and reliable form of narcotic for patients with toxic goitre.

EXPERIENCE WITH RECTAL AVERTIN

Our first experience of the use of avertin in toxic goitre was gained in treating a patient who was one of the most seriously ill that I have seen.

A boy aged 17 was under treatment by Dr. Langdon Brown in St. Bartholomew's Hospital. His physical and mental development were those of a boy of 12, and there were no signs of puberty. Exophthalmos was extreme, and all the other signs of toxic goitre were fully developed, with enlargement of the heart, frequent attacks of vomiting, and great nervous irritability. His metabolic rate was estimated to be only +34 per cent., but he was nevertheless obviously extremely ill, with a pulse rate of 100 to 130 in bed, rising occasionally to 160 or 170. After he had been under treatment for nearly four weeks his condition was worse rather than better. His general pulse level had risen to 130 to 150, and it was clear that he would soon die if nothing further were done. An operation was therefore undertaken on December 31st, 1929, for ligature of the superior thyroid arteries, the anaesthetic being local infiltration with 0.5 per cent. novocain followed by gas and oxygen. The patient was exceedingly apprehensive, and reacted violently to this interference. His pulse rate rose to 200 and remained in the neighbourhood of that figure for thirty-six hours, and he was restless and noisy. He barely survived, but his condition eventually returned to much the same level as before the operation. It could not be said that he was really any better than this when a second operation was undertaken three weeks after the first. On this occasion, however, he was given rectal avertin to the amount of 0.1 gram per kilo of body weight, and was soundly asleep when put on the operating table. After the neck had been infiltrated with novocain the right lobe of the thyroid was removed, no further anaesthetic being required. His pulse rate at the beginning of the operation was 172, and at the end 140. His pulse rate did not rise after this time above 160, and there was no further reaction. He steadily improved, and a month later the greater part of the second lobe was removed, again under avertin, though on this occasion narcosis was not so deep, and gas and oxygen had to be given in addition. The patient has since made a complete recovery, with rapid mental and physical development, though I received the impression that without the help of avertin he would not have survived the second operation.

We accordingly resolved to employ rectal avertin systematically for patients with toxic goitre, and this communication is based on experience of its use in patients operated upon since January 1st, 1930, at St. Bartholomew's Hospital, at the L.C.C. Thyroid Clinic, New End, or in nursing homes. We agreed from the start that no attempt should be made to obtain full anaesthesia with rectal avertin, but that it should be regarded only as a basal narcotic, and should be supplemented as a routine by a local infiltration of the neck with novocain and, whenever necessary, with gas-and-oxygen inhalation. It was also agreed that no risk of respiratory depression should be introduced by excessive premedication, though a small dose of morphine should precede the avertin as a general rule. We hoped by these means to achieve the blissful state of having the best of both worlds—that is to say, of totally eliminating mental disturbance in the patient while giving the surgeon the advantage of having an unconscious patient whose welfare was not

being endangered by the absorption of any drug in sufficient quantity to produce toxic effects.

Each patient has accordingly received morphine 1/8 grain two hours before operation and 1/12 grain one hour before, or, more frequently, a single injection of 1/8 grain one hour before operation. The danger of producing respiratory depression by giving larger doses than this has unfortunately been demonstrated more than once, in spite of warnings by Sir Francis Shipway and others. In our series no patient has ever given anxiety from this cause, so that morphine 1/8 grain appears to be a safe dose, though probably it is not essential to give any morphine at all.

Forty-five minutes before operation the patient is given avertin solution per rectum to the amount of 0.09 or 0.1 gram per kilo of body weight. In four patients of the present series the amount was increased to 0.11 gram, but in others, if the patient was heavy, less than the calculated amount was administered. The larger total is given to the more acutely toxic patients and the smaller to those that are less ill, for it is noticeable that individuals with a metabolic rate that is much above normal are less deeply narcotized by a given dose than are those with a lower metabolic rate. This constitutes an additional safeguard in using avertin for toxic goitre, and it seems to be clear that an upper limit of 0.1 gram per kilogram constitutes a safe dose, since no patient in our series has been unduly narcotized. All the patients have been unconscious when brought on to the operating table except one, who was suffering from diarrhoea and was unable to retain more than a fraction of the dose. On this occasion the operation was not performed, but was done on another day with the help of omnopon and hyoscine instead of avertin.

When the patient has been placed on the operating table the mask for gas-and-oxygen administration is fixed in position on the face, but as a rule no gas is given at this stage. The skin is cleaned, towels are put in position, and the operation area is then infiltrated with 0.5 per cent. novocain solution in normal saline containing 1 in 500,000 adrenaline hydrochloride. It is quite unnecessary to use a solution of greater concentration than this. With the help of a Dunn's self-filling syringe the infiltration is rapidly effected, and as the volume of solution used is usually in the neighbourhood of 100 c.cm. to 150 c.cm. the total amount of novocain given is about 0.5 gram to 0.75 gram, and no patient, so far as I know, has ever suffered any deleterious effect from it.

For some of the more mildly toxic patients this combination of basal narcosis and local infiltration with novocain is all that is needed, but in fewer than 10 per cent. is the operation completed without any gas and oxygen being given. Some of the more acutely toxic patients are disturbed by their removal from the trolley to the operating table; others are roused by the first prick of the local anaesthetic needle; and yet others remain quiescent until half-way through the operation. Once the patient has been roused she is, although still unconscious in the ordinary sense, always uncontrollably restless, so that gas and oxygen is begun at once whenever this occurs; but an expert administrator can, with this combination of drugs, maintain perfect anaesthesia with a minimal amount of gas, and can entirely avoid cyanosis. It is particularly important that the patient should not be allowed to become cyanosed, experience having taught me that there is no factor more potent in producing a rising pulse rate in a toxic patient.

When the patient is back in bed, after the completion of the operation, she usually remains quiescent for two or more hours, so that mental disturbance is eliminated at this stage as effectually as before, and this constitutes another important advantage in the use of avertin.

In the days of ether anaesthesia and of conscious patients with a novocain infiltration, I was accustomed to seeing the patients leave the operating table with a somewhat high pulse rate, which was an indication of an unfavourable reaction to the procedure. Under avertin narcosis the pulse rate may rise a little with the initial disturbance and the induction with gas and oxygen, but not infrequently the pulse rate is actually lower at the conclusion of the operation than at the beginning, which is a truly remarkable reversal of the usually accepted effect of operative intervention. Very seldom is there any alarming rise of pulse rate during the operation, and the post-operative reaction is correspondingly mild and transient. This appears to me to be one of the greatest of the benefits conferred by the use of avertin, since there is seldom any anxiety period for patient, nurse, or surgeon. In a few patients unusual events were noticed, and it is of interest to describe these in detail as perhaps throwing light on the question as to whether avertin in moderate dosage is ever really deleterious to toxic patients.

A patient, aged 25, with a resting pulse rate of 100 to 130, was given the usual dose of avertin (0.1 gram per kilo). She was restless from the start, and before the operation had begun the pulse rate had risen to 140. The operation was therefore limited to ligation of the right superior thyroid artery. The pulse fell to 80 to 90 within forty-eight hours, and seven days after the first operation the right lobe of the thyroid was removed, the pulse rate on this occasion rising to 130. Improvement again followed. A fortnight later avertin was again given, and on this occasion the pulse rate immediately rose to 160. Again, therefore, no more was done than to ligature the left superior thyroid artery. Ten days later avertin was given for the fourth time, and the operation was completed without causing the pulse rate to rise above 120.

At the third operation it might have been concluded that the extreme rise in pulse rate was due to the avertin, but that this conclusion would be erroneous seems to be shown by the following:

A patient, aged 22, with a severe degree of toxic goitre and a resting pulse rate of 100 to 140 was treated medically in hospital for over three weeks without any improvement at all. Her pulse remained exceedingly irritable, and her average pulse rate was higher after three weeks than when she was admitted. It was therefore decided to operate in stages without further delay. She was given the usual dose of avertin, and the right superior thyroid artery was ligatured under local anaesthesia and gas and oxygen. The pulse rose to 160, and remained for three days at 150 to 160, after which it fell to the same level as before. A week later the left superior thyroid artery was tied as before, the pulse rate on this occasion remaining for three days at 130 to 150, after which there was considerable improvement. A fortnight later the patient was given avertin for the third time, and the right lobe of the thyroid was removed. The reaction was relatively mild, the pulse not rising above 140. After another fortnight's interval avertin was given for the fourth time, and on this occasion the pulse rose to 180 before the operation had begun, and the patient was immediately returned to the ward. This extreme rise in pulse rate was difficult to explain, but it was suggested that it might be in some way due to the repeated doses of avertin. It was therefore decided to perform the last stage of the operation without avertin, and to give only morphine $1/4$ grain and scopolamine $1/100$ grain, local anaesthesia and gas and oxygen being given on the operating table. The rise in pulse rate, however, was much as before, and for three days remained at 130 to 160. Within ten days after the operation had been completed the pulse rate was normal, and the patient has been virtually cured since that time.

It appears, therefore, that this patient had an unusually irritable heart, and that its rapid rate was to be attributed to its being sensitive to minor disturbances rather than to any specific effect of the avertin. It would appear, indeed, from the following case that if any specific effect

on the heart is produced by avertin it will be a sedative rather than an irritative effect.

A patient, aged 16, who was under treatment at the L.C.C. Thyroid Clinic at New End, had already had all four thyroid arteries tied by Sir Thomas Dunhill. In spite of this she remained in a state of severe mental derangement, and showed a resting pulse rate for week after week of 140 to 180. No improvement was being obtained, and I therefore decided, in Sir Thomas Dunhill's absence, to operate in spite of the rapid pulse rate. She was given avertin, and immediately the rate fell to 120. It remained at about that level throughout the operation for removal of the right lobe of the thyroid, and rose again to 140 when she regained consciousness. Twelve weeks later she was again given avertin for the final stage of the operation, and again her pulse rate fell to a much lower level during the operation. Her later history was one of steady recovery, and she was discharged from hospital quite sane and with a pulse of 110.

The sedative effect of the avertin narcosis in this patient was most striking and reassuring.

SUMMARY AND CONCLUSIONS

The primary object of using the somewhat complicated anaesthesia technique that I have described was, of course, the reduction of operative mortality to as near zero as possible. That this object has been achieved is suggested by the fact that of the 220 patients who have been operated on under avertin narcosis only three have died soon afterwards. One of these was a woman of 24, who was clearly acutely ill and rapidly losing ground, so that operation was undertaken lest worse befall. The operation under avertin was successfully performed without any undue disturbances. On the day following, however, the pulse rate rose to 170, and remained about this level for over forty-eight hours. She then rapidly improved, and by the sixth day after operation all danger seemed to be over. On the seventh day, however, vomiting started, and the patient died twenty-four hours later in a condition resembling acute dilatation of the stomach. A critical review of the case afterwards suggested that the real cause of death was probably digitalis poisoning, the resident medical officer having given nine injections of digitalin $1/240$ grain in the course of five days.

Of the other two patients who died one had gross auricular fibrillation and died from heart failure a few hours after the operation. The other was so ill that she developed an acute thyroid crisis a few hours after the ligation of one superior thyroid artery, and quickly died.

The immediate operative mortality among these patients has therefore been less than 1 per cent., and it can be claimed that this low figure has not been obtained by any selection of patients. Some of them have been mildly toxic, but a large proportion have been seriously ill, and operation has never been refused when asked for by a medical colleague, even when the reason for operation was the patient's desperate condition. In nineteen cases the patient was so ill that the operation was performed in two or more stages. Twenty-four patients were suffering from gross auricular fibrillation. Judged by ordinary standards the "operative risk" in most cases was considerable, and I cannot avoid the conclusion that the low mortality is to be attributed, to some extent, to the systematic use of rectal avertin.

My patients, therefore, owe a very great debt of gratitude to the skill of the nursing staff who have attended them and to the anaesthetists with whom I have collaborated. The majority of the anaesthetics were supervised or administered by Dr. C. Langton Hewer, Dr. Frankis Evans, and Mr. Brian Rait-Smith. The anaesthetics at New End were given by Dr. E. A. Seymour.

ELECTROCARDIOGRAPHIC CHANGES DURING BRIEF ATTACKS OF ANGINA PECTORIS

BY

MALCOLM K. GRAY, M.B.(N.Z.), M.R.C.P.LOND.

PHYSICIAN IN CHARGE OF THE CARDIOGRAPHIC DEPARTMENT,
CHRISTCHURCH HOSPITAL, NEW ZEALAND

Large numbers of electrocardiograms of attacks of cardiac infarction have been published, but there are relatively few of the brief attacks of angina pectoris. This is due, no doubt, to the infrequent opportunities which arise, but the records are of importance in throwing light on the mechanism of production of the pain.

Levine, Ernstene, and Jacobson¹ published a series of electrocardiograms taken during attacks of angina produced by injections of epinephrine. They did not find any specific changes, the only modification being a differ-

knowledge of the effect of the drug itself on the electrocardiograms during the attack.

CASE RECORDS

Case 1.—A female, aged 62, first seen in June, 1932, when she complained of precordial pain radiating to the left arm. She had had the pain for two years, but it had become worse recently. It was induced by exertion or excitement, and was always relieved by rest. The heart was not enlarged, and the sounds were normal. Blood pressure: 160/80. Prolonged rest benefited her, but in March, 1933, she became gradually worse, and during an examination of the heart she had an attack which she described as being quite typical. The pain was relieved by ten minutes' rest, and with adequate rest she has since remained fairly well. The electrocardiograms are reproduced in Fig. 1. (A) was taken immediately after the commencement of the attack, and (B) some time later, when the patient was free from pain. (A) shows a depression of the RT interval in Leads 1 and 2, and an elevation in Lead 3. The amplitude of QRS is slightly increased. (All electrocardiograms are standardized 0.2 sec. \times 0.2 cm.)

(A) FIG. 1. (B)

(A) FIG. 2. (B)

(A) FIG. 3. (B)

ence in size of the waves without any change of direction. These attacks were artificially produced, and it would be unwise to apply their conclusions to a "naturally" produced attack. Parkinson and Bedford² summarized the literature to date, and reported five cases of brief attacks of angina in which electrocardiograms had been taken during and after the paroxysm. There was a depression of the RT interval and a diminution or an inversion in T waves in one or more leads. They did not suggest that these changes were present in all cases. Wood and Wollerth³ reported thirty cases, fifteen of which showed changes in the T wave during the attack; seven of these were severe and eight were mild attacks. The changes consisted of an alteration in height of the T wave, or a change from positive to negative, and the appearance of a depression in the RT interval. In the electrocardiograms reproduced Charts 8 and 12 showed the depression of the RT interval. The authors mentioned this as occurring in five other cases, but no charts were given. Fifteen cases showed no change. They also completed a series of animal experiments, and their conclusions were that the majority of the attacks of angina were associated with a localized circulatory disturbance in the heart. The possibility of other mechanism was not definitely ruled out.

The records of four cases are given below; all the patients had an attack in the consulting room. The attacks were probably induced by excitement, as there was no preceding exertion, and were relieved by rest, the longest time for complete cessation of pain being twenty minutes. Amyl nitrite was not used, as there is no

Case 2.—A female, aged 72, first seen in October, 1931, when she complained of substernal pain radiating in both arms, but worse on the left side; duration four to five months. The pain was always induced by exertion or excitement, and relieved by rest. There was some dyspnoea at night, which was relieved by sitting up. The heart was slightly enlarged, and was half an inch beyond the mid-clavicular line. There were no murmurs; aortic second sound increased. Blood pressure: 250/140. While the examination was in progress the patient complained that the pain was beginning. It developed into a typical attack, which was relieved by ten minutes' rest. After rest she has since remained well. The electrocardiograms are reproduced in Fig. 2. (A) was taken at the height of the attack, and (B) half an hour later, when the patient was free from pain. (A) shows a depression of the RT interval in Leads 2 and 3. The amplitude of QRS is increased. A further electrocardiogram taken in November, 1931, was identical with (B).

Case 3.—A female, aged 53, first seen in March, 1932, when she complained of a dull, aching precordial pain radiating to the left arm, induced by exertion and relieved by rest; duration eighteen months. Less exertion was required to produce the pain than a year previously. The left border of the heart was one inch beyond the mid-clavicular line; there were no murmurs. Blood pressure: 175/95. During the examination the patient had a typical attack, which was relieved by rest in a very short time (about five minutes). A prolonged rest has given her freedom from pain. The electrocardiograms are reproduced in Fig. 3. (A) was taken during the attack, and (B) following it. (A) shows a depression of the RT interval in Leads 1 and 2. The amplitude of QRS is slightly increased. (B) shows no depression in Lead 1, but a slight depression in Lead 2.

Case 4.—A man, aged 62, first seen in January, 1932; he complained of substernal pain radiating to both arms, of six years' duration. The pain was much more easily produced in the last year; moderate exercise, such as light digging, brought it on, and it lasted for two to three minutes. It was always relieved by rest. The left border of the heart was in the mid-clavicular line; there were no murmurs. Blood pressure: 180/90. During the examination the patient had an attack, which he described as being rather worse than usual. It was relieved by twenty minutes' rest. He now keeps well with adequate rest. The electrocardiograms are reproduced in Fig. 4. (A) was taken during the attack and (B) following it. (A) shows a depression of the RT interval in all leads, particularly in Leads 2 and 3.

(A) FIG. 4. (B)

DISCUSSION

In these four cases definite changes in the ventricular complexes of the electrocardiograms are demonstrated. These changes resemble those produced by coronary thrombosis. It is agreed that they are not always present, due no doubt to "silent areas" in the myocardium, changes in which do not affect the electrocardiogram. The positive evidence adduced in the above cases and in those previously published points very strongly towards the coronary origin of anginal pain.

The Italian Fascist National Federation Against Tuberculosis has again placed at the disposal of the International Union Against Tuberculosis six scholarships at the Benito Mussolini Institute in Rome. The conditions submitted are as follows: These competitive scholarships, of a value of 6,000 lire respectively, plus board and lodging, are intended to enable foreign medical practitioners to stay at the Benito Mussolini Institute in Rome for the purpose of following a course of studies. This stage of eight months will correspond with the academic year (from November 15th to July 15th), including the usual holiday periods. The scholarships will preferably be awarded to young physicians already familiar with tuberculosis problems who wish to improve their knowledge of this branch of medicine. The kind of work undertaken at the Institute will be subject to an agreement between the director and the candidate. The publication expenses resulting from this work may be defrayed partly or entirely by the Institute. The scholarships will be awarded at the summer session of the Executive Committee of the International Union, which meets this September. No candidature will be considered unless it has been forwarded by an association belonging to the International Union. The body representing Great Britain and Northern Ireland is the National Association for the Prevention of Tuberculosis, Tavistock House North, Tavistock Square, London, W.C.1, to whom applications should be sent not later than July 1st, giving particulars as to age, qualifications, and professional experience.

MAGNESIUM DEFICIENCY IN THE RAT

BY

RONALD W. BROOKFIELD, M.D., Ph.D.
M.K.C.P., D.P.H.

HONORARY ASSISTANT PHYSICIAN, ROYAL SOUTHERN HOSPITAL,
LIVERPOOL; BRITISH MEDICAL ASSOCIATION RESEARCH
SCHOLAR, 1929-31

(From the Department of Biochemistry, University of Liverpool)

The intensive study of calcium metabolism, for which the investigations of rickets and tetany carried out in recent years have been chiefly responsible, has not stimulated significantly inquiry into the part played in the organism by magnesium, which so closely resembles calcium in its chemical properties. Whereas the concentration of magnesium in serum is of the order of 2 mg. per 100 c.cm. as compared with 10 mg. of calcium, its concentration in muscle, which accounts for so large a part of the body weight, is four times as great as that of calcium—that is, 20 mg. as compared with 5 mg. The distribution of the two constituents in the tissues suggests that magnesium plays a part in physiological processes not less important than that played by calcium. Nevertheless, it is only comparatively recently that magnesium has been shown to be necessary to life.

Leroy¹ found that when mice were fed on a diet containing 1.03 mg. of magnesium in 100 grams, death occurred in twenty-four to thirty-five days, and his work has been considerably amplified by Kruse, Orent, and McCollum,² who, using a diet which contained only 0.18 mg. of magnesium in 100 grams, have studied the symptoms and some of the biochemical changes which result when rats and puppies are deprived of magnesium. Cramer,³ by placing young rats on a diet in which the amount of magnesium was reduced to 0.632 mg. per 100 grams, showed that degenerative changes occur in the kidneys as a result of magnesium deficiency. I have been engaged on a biochemical and pathological study of magnesium deprivation, and have utilized for this purpose a small group of rats. The findings are of interest in that while the convulsive phenomena described by Kruse, Orent, and McCollum have been confirmed, the cutaneous manifestations, which are regarded by these workers as one of the distinctive features of magnesium deprivation, have been entirely absent. Moreover, histological examination of the organs has revealed marked pathological changes in the liver, as well as changes in the kidneys somewhat similar to those reported by Cramer.

EXPERIMENTAL

A diet composed of a mixture of casein, starch, butter-fat, vitamins, and salts, freed from magnesium by the methods employed by Kruse, Orent, and McCollum, was given to eight young black-and-white rats weighing from 65 to 107 grams. Four other rats, which served as controls, received the same diet with the addition of magnesium sulphate. The animals took the diet well and increased in weight for a short period. Later the weights of both test and control rats tended to remain stationary or to fall slightly. On the twenty-second day of the experiment Rat 1, which had been quiet for some days, was found dead in its cage, and two days later Rat 3 was found in a moribund condition. On the twenty-seventh day the first convulsions were observed in Rats 7 and 8, which had previously appeared entirely normal. After going round in circles for a short period Rat 8 dived under its feeding dish and went into generalized convulsions, a tonic being followed by a clonic stage. A second slighter convulsion occurred after the first. The convulsive attack of Rat 7 was milder, but otherwise similar. Both animals recovered completely

after an hour's quiescence. Later in the same day Rat 5 had a convulsion which appeared to be induced by the noise made by the setting in motion of a vacuum pump. Two seconds later Rat 7 again went into convulsions. In both these animals the spasms were of considerable severity, and were reminiscent of insulin convulsions in the rabbit. The animals were hurled with great violence from side to side of their cages during the tonic stage. In the clonic stage they attempted to climb up the walls of their cages, but appeared to be too weak to do so. A phase of champing of the jaws followed, and afterwards the animals lay on their flanks apparently unconscious. Rat 5 recovered quickly, but Rat 7 had a few further clonic spasms an hour later and died.

Rat 2 died on the thirty-first day after three successive attacks. The clonic stages were prolonged, the forepaws being continuously crossed, while the jaws showed champing movements with drooling of saliva. On the thirty-sixth day Rat 4 developed oedema of the paws, and had a mild convulsion; it died after a further slight seizure five days later. Rat 8 was found dead on the thirty-eighth day, while Rat 5 died rapidly after a very mild attack on the forty-first day. These two animals, therefore, survived eleven and fourteen days after their first observed convulsion. The sole surviving test animal, Rat 6, was killed on the fiftieth day; it was never seen in a convulsion. The control animals, which remained in good condition, were killed about the same time.

PATHOLOGICAL CHANGES

Rigor occurred very rapidly. Dissection of the rats failed to reveal any abnormality visible to the naked eye. The livers and kidneys of Rats 4, 5, and 6, and of a control rat were examined microscopically, and the writer is indebted to Dr. R. Howard Mole, pathologist to the Royal Southern Hospital, for the histological details which follow.

Livers.—In each of the test animals the cytoplasm of many of the liver cells gave the appearance of being partially disintegrated, and had taken on a honeycomb structure. This change was most widespread in Rat 6. In this animal, too, a few scattered cells showed nuclear karyorrhexis. In Rat 5 the cytoplasmic change was focal in distribution and intervening cells were normal. In Rat 4 only slight cellular change was evident.

Kidneys.—Rat 5 exhibited profound changes in both glomeruli and tubules. The capsular lumen contained a large amount of detritus, which had compressed and pushed to one side the capillary tuft. In glomeruli less severely affected the cells lining the capsule were found to be swollen and desquamated. No normal tubules were seen. The epithelium was necrotic, and nuclei were almost absent. There was no increase in connective tissue and no calcification. In Rat 6 there was a moderate amount of parenchymatous change in the tubule cells, and a similarly moderate change in the glomeruli. Rat 4 exhibited very slight glomerular and tubular change. It is noteworthy that this was the only animal which showed any evidence of oedema during life. The renal findings resemble those of Cramer, but the degeneration is more widespread than in the sections illustrated by him. The calcification which he found so marked a feature was absent.

DISCUSSION

The findings recorded above are in general agreement with those of Kruse, Orent, and McCollum. My own results differ, however, in one important respect. The American workers have described a state of intense hyperaemia of the skin, which preceded the onset of the convulsions by some days. Moreover, in those animals which survived for a longer period they noted thinning of the coat and other trophic changes. In the present investiga-

tion no vasomotor or trophic phenomena were observed, if the oedema noted in Rat 4 be excepted. The weights of the animals were about twice as great as those of the majority of animals employed by Kruse, Orent, and McCollum. This fact doubtless accounts for the longer period which elapsed (twenty-one days or more as against their average of eighteen days), before the motor symptoms of magnesium deprivation became manifest. The American workers found that only 14 per cent. of the younger animals survived the first attack of convulsions, but that in the case of older rats the number of survivors was greater. In harmony with this observation three out of seven of the animals in the present series lived for periods of from five to fourteen days after the first attack, and may possibly have had other attacks while not under observation before they finally succumbed.

A further interesting feature was that, as the experimental period became more prolonged, the convulsions were less severe, even though fatal results ensued. Rats 4 and 5, the last animals to succumb, each died after a very slight attack. In Rats 3 and 7 opacities were seen to form in the lens a few minutes before death, but though the eyes of all the surviving animals were examined by Mr. A. McKie Reid with the help of the slit-lamp, no pathological changes were detected, nor did any of the animals which died subsequently exhibit the premortal opacities.

The mechanism whereby the convulsions are induced naturally calls for some explanation. Kruse, Orent, and McCollum believe that they are a form of tetany. It is generally recognized that deficiency of calcium upsets the balance of ions in the tissue fluids and leads to increased irritability of the nervous system, and they contend that the effects of magnesium deficiency are of a similar character. Differences in detail between the symptomatology of calcium and magnesium tetany they ascribe to the different degrees of irritability of the various tissues. That there are considerable differences in the manifestations of the two deficiencies is evident. In low calcium tetany the peripheral nerves are most characteristically affected, with the production of carpopedal and laryngeal spasm. In magnesium deficiency the motor phenomena appear to result from central irritation. Thus in the present investigation the convulsions came on with great suddenness, were generalized, and, when severe, left the animal unconscious for a short period. They were, in fact, typically epileptiform. In this connexion it may be noted that Meltzer and Auer¹ have shown that the injection of magnesium salts causes narcosis, and if the brain is depressed by an excess of magnesium it seems not unreasonable to suppose that it will be rendered hyperexcitable by a deficiency of the same element.

Whether the lesions in the kidneys or liver have any direct relation to the convulsions cannot yet be stated with any certainty. It seems highly probable that these lesions are responsible for the changes in the blood fat and the terminal rise in the blood non-protein nitrogen which have been reported by Kruse, Orent, and McCollum. It may ultimately be found, therefore, that the convulsions are due, not to tetany, but to renal and hepatic dysfunction.

SUMMARY

1. Convulsive phenomena occurring in rats deprived of magnesium are described.
2. The cutaneous changes reported by other workers have not been observed.
3. Acute degenerative changes have been found in the liver and kidney.

Clinical Memoranda

THREE CASES OF CATARRHAL JAUNDICE DEMONSTRATING THE INCUBATION PERIOD

The clinical similarity of these three cases makes it obvious that the patients suffered from the same disease.

Case 1.—A boy, aged 12. On January 9th, 1934, had pharyngitis and definite tonsillar enlargement, but no pus issuing from the tonsillar fauces. The uvula and soft palate were oedematous. Temperature 101° F. Two days later the throat condition had begun to settle down, when bile appeared in the urine. Two days later the child became jaundiced. The liver at this time was enlarged and tender, but there was no enlargement of the spleen. The stools were pale.

Case 2.—A girl, aged 15. On January 29th had pharyngitis, but no tonsillar infection, since these structures had been removed. The uvula and palate were red and oedematous. Temperature 100° F. Two days later the urine contained bile, but not so much as in Case 1, nor was the jaundice, which followed on February 2nd, so severe.

Case 3.—A man, aged 24. Had enlarged and red tonsils on February 18th, with a temperature of 102° F. The pharyngeal appearance was interfered with here because the patient had had a repair for a cleft palate as a child. On February 20th the urine contained much bile, and two days later the patient became deeply jaundiced. His liver was enlarged and tender, but there was still no enlargement of the spleen.

These patients were in the same family, and they all started with an upper air-passage infection. The incubation period was twenty days, and the source of infection the throat. The appearance of the throat was similar, but it is noteworthy that the girl, who had had her tonsils removed, did not have such a severe infection as the others.

Birmingham. ARTHUR BEAUCHAMP, M.R.C.S., L.R.C.P.

TORSION OF FALLOPIAN TUBE DURING PREGNANCY

The following case of torsion of the Fallopian tube, an example of which was described by Mr. A. McEachern in the *British Medical Journal* of February 3rd, derives additional interest from the fact that the patient was well advanced in pregnancy.

A woman aged 30 was admitted to the Preston Infirmary on December 4th, 1933, complaining of severe pain on the right side of the abdomen. She was about six months pregnant, it being her first pregnancy. The pain had begun about forty-eight hours before admission, and there was said to have been a rigor at the commencement.

The tongue was dry, pulse 94, temperature 98.6° F. The abdomen, which was enlarged to about the usual size for six months' pregnancy, was held rigid, but not continuously so. There seemed to be some tenderness all over, but it was most marked and definite on the right side. Sugar and pus were reported in the urine. There did not seem to be any peritonitis at the site of the pain, as the abdominal wall relaxed and moved normally when the patient was not holding herself tight. An enema was given, with good result. Large doses of pot. cit. were prescribed.

The pain continued the next day. The urine on laboratory examination contained 0.5 per cent. of glucose and ketones, but no pus. Blood sugar was 85 mg. per 100 c.cm. The temperature was never above 98.8° after admission. On December 6th, as the pain continued, cystoscopy was performed, since there seemed a possibility that the pain was due to right renal colic. Nothing abnormal was found, however; a catheter passed readily up the right ureter, and both ureters discharged intravenous dye in normal time.

On palpating the abdomen with the patient anaesthetized, a kind of knob was felt on the right side of the uterus, but I did not associate this with the patient's illness. After the negative cystoscopy, however, I decided to open the abdomen, and did so in the region of the right semilunar line. A black

mass, the knob which I had felt, was seen attached to the enlarged uterus, being the swollen and congested Fallopian tube, the pedicle showing well-marked torsion anti-clockwise. The mass was about the size of an infant's fist. The coils of the twist nearest the uterus were pale, those more distal being black, like the rest of the tube. The tube was removed and the abdomen closed. The patient recovered, and was discharged on December 23rd. There was no glycosuria subsequent to the operation. She reported fit at an antenatal clinic at the end of January, and is expecting admission to the maternity department about March 20th.

The first report of pus in the urine after ward examination was probably in error, as none was found subsequently on repeated examination. According to the diagram accompanying Mr. McEachern's account of his case the whole length of the tube appears to have been twisted. In the case just described the twist was concentrated in the narrow pedicle.

W. MCKERROW, M.B., F.R.C.S.,
Surgeon, Royal Infirmary, Preston.

CIRRHOSIS OF THE LIVER IN A BABY

Cirrhosis of the liver is rare in childhood. Graham Forbes' records the occurrence of forty cases among 5,500 post-mortems carried out at Great Ormond Street over a period of forty-five years. The cases that have been recorded have mainly occurred in later childhood, and the youngest case that I have been able to find in the English literature in which the diagnosis was confirmed by post-mortem examination is the one recorded by Sir Thomas Barlow in 1834,² in which the condition was seen in a baby of 18 months. In the following case the condition was found post mortem in a baby 1 year old, and therefore seems worthy of record.

The baby was born on January 15th, 1932, and was full-time and weighed 8 lb. The pregnancy and labour were normal. It was breast-fed, and progressed normally till the age of 8 months, when it weighed 17 lb. At that time, however, while still on the breast, it commenced to go downhill. It changed from being a happy and contented baby, and became fretful. There was no vomiting or diarrhoea, and it continued to take its food well. It was then admitted to another hospital without a definite diagnosis being made. On January 2nd, 1933, it was admitted to a fever hospital with a diagnosis of nasal diphtheria, and was discharged on January 21st.

On February 8th the child was admitted to Hammersmith Hospital. It was then extremely marasmic and restless. Temperature 100.6°, pulse 168, respirations 32. There was a small haemorrhage in the left cheek, and a swelling in the lower part of the left forearm, which x-ray examination showed to be due to callus from an old fracture. Two days later the child was very collapsed, and had head retraction and a haematemesis. On lumbar puncture clear fluid under pressure was obtained. The child died the same day.

On post-mortem examination the liver was found to be yellow, and contained several small haemorrhages. It presented the typical "hobnail" appearance found in adults in cases of multilobular cirrhosis. The microscopical report was as follows: "Fatty degeneration, and fine-fibred coarse-meshed fibrosis of liver. The cirrhosis is almost certainly due to toxic absorption." The spleen was large and congested, and the kidneys were fatty. Haemorrhages were present in the stomach. The intestines presented no abnormality, and there was no mesenteric lymphadenitis. The lungs showed bronchopneumonia.

The aetiology of this case presents an interesting problem. In most of the cases described in the literature there is a definite history of alcohol, usually in the form of spirits, having been given. In the case described by Sir Thomas Barlow gin had been taken over a prolonged period, and Ernest Jones³ found that alcohol had been administered in every single one of seventy-two cases reported in

the literature. In the case described above no such history was obtained. Apart from the illnesses mentioned, there had apparently been no other aetiological factor, such as gastro-enteritis, in which a fatty liver is commonly found. There had been no previous jaundice. Unfortunately no Wassermann reaction was done, but there was no other evidence of syphilis. In the absence of further definite knowledge one can only explain the condition on the vague theory of "toxic absorption."

I am indebted to Sir Thomas Carey Evans for permission to publish this case, and to Dr. W. G. Barnard for the histological report.

BRYAN WILLIAMS, M.B., F.R.C.S.ED.

CYST OF THORAX OUTSIDE THE PARIETAL PLEURA*

The patient was a man aged 63, who died in November, 1933, with extensive carcinomatosis (possibly primary) of the liver. Radiographic examination of his thorax during life had shown two closely adjacent spherical bodies (one larger than the other), situated just above the diaphragm in the left outer part of the thoracic cavity. These had been likened to two billiard balls. The post-mortem examination showed, besides the carcinomatosis of the liver and of some lymphatic glands, that the spherical radioscopic shadows were due to a bilocular, serum-containing cyst. The cyst (see figure) was situated in the loose connective and fatty tissue above the extreme left part of the diaphragm (on which it rested); it was outside the parietal pleura, which covered it. The lung was indented by the cyst, but there was no adhesion of the two layers of the pleura over it.

Macroscopical Examination.—The wall of the cyst was fibrous, with an endothelial lining—a single layer of cells in some parts, stratified endothelium in others; outside was connective tissue, with some fat and many solitary lymph follicles containing well-marked Flemming's "germ centres." Some of these lymph follicles actually formed part of the cyst wall, reminding one of the intimate relation of lymphadenoid tissue to the cyst wall in many cases of so-called branchial cysts of the neck.

Remarks.—This bilocular cyst seems to have been due to a congenital abnormality of development—namely, the formation of two pleural pockets—which afterwards became completely cut off from the main pleural cavity. It is correct in this view, the cyst in this case may be likened to certain serous cysts of the peritoneum, which are lined with endothelium similar to that lining the peritoneum. We have not found any published description of similar pleural cysts.

F. PARKES WEBER, M.D.
E. SCHWARZ, M.D.

* This case was demonstrated at the pathological evening of the Medical Society of London, January 8th.

Reviews

ENDOCRINE SYNDROMES

Professor NOËL FIESSINGER's introductory remark to his *Physiopathologie des Syndromes Endocriniens*¹ that endocrinology is "rapidly becoming a science where imprecision is united to fantasy," prepares us for a certain Gallic crispness of style. But when the reader finds the statement that "pathology is in effect the kingdom of endocrine interdependence," he may take alarm and feel that here is an enthusiast indeed. We may hasten to reassure him, for the author extends the sphere of endocrinology so widely as to make it practically synonymous with internal metabolism, in which case we may be prepared to accept his statement. Thus he includes the spleen, the kidneys, and the reticulo-endothelial system in this category, in addition to all the functions of the liver. Perhaps where the subject is specifically that of syndromes, this may be justifiable, and it certainly widens the scope of the book.

We are interested to note that the syndrome usually known as Fröhlich's is labelled also with the name of Babinski. This is historically correct, for Professor Harvey Cushing has recently reminded us that while he and Fröhlich were working in Professor Sherrington's laboratory in Liverpool in 1900, Babinski, unknown to either of them, published the first case of this syndrome that was recognized. Fröhlich, returning to Vienna in the next year, reported a similar case more fully, which excited much attention, and so his name has generally been associated with it. Babinski, however, has undoubted priority. It is, in a way, unfortunate that both these authors reported cases of chromophobe adenomas as being responsible for the syndrome, because this led to a very sinister prognosis being attached to it, whilst we now realize that there are many cases of Fröhlich's syndrome which are due to a delayed differentiation of the chromophobe cells. A chromophobe adenoma will impair the eyesight, but such a diagnosis should not be made in the absence of pressure symptoms and an enlarged pituitary fossa.

Another interesting point in nomenclature is the revived tendency to apply the name of von Recklinghausen to generalized osteitis fibrosa. His name has been so long associated with another syndrome that it is rather confusing to apply it to cases of hyperparathyroidism producing bony changes, for although he recognized these changes, he did not know of their association with the parathyroids.

Enough has been said to show the wide range covered in this book, which we can cordially recommend as an interesting presentation of the subject.

SURGICAL NEUROPATHOLOGY

We have received the first two volumes of *Chirurgische Neuropathologie*, by Professor L. PUSSER, director of the University Nerve Clinic in Tartu (Dorpat). This important work is based on the author's thirty years' experience as neurologist and neurological surgeon not only in peace time, but also in the Russo-Japanese War and in the Great War.

The first volume, in two parts, deals with the peripheral nerves; it comprises 662 pages, and is divided into a general section and a special section. In the general section are described the most important anatomical and physiological details, and the general surgical pathology.

¹ *Physiopathologie des Syndromes Endocriniens*. Par Professeur Noël Fiessinger. Paris: Masson et Co. 1933. (Pp. 518; 42 figures, 42 fr.)

of the peripheral nervous system. The surgical approach to each peripheral nerve is then given in detail, with explanatory diagrams, followed by a description of the operative procedures which can be carried out on nerves. The various methods of nerve testing are described in detail. The special part is devoted to wounds of the peripheral nerves, with the results of operative treatment, tumours of the nerves and their treatment, operations on the peripheral nerves for certain reflex conditions, and various operations that can be carried out on the nerves for the diminution of pain, including the injection and operative treatments of the different forms of neuralgia of the various nerves. Volume ii comprises injuries and diseases of the spinal cord, and of the spinal column in so far as the latter affect the former. The general part, comprising 233 pages, is devoted to a description of the anatomy and physiology of the spinal cord, the cerebro-spinal fluid, modern methods of diagnosis, and the symptomatology of the surgical diseases and injuries of the spinal cord. The special part consists of nearly 400 pages, devoted to an exhaustive account of the injuries and diseases of the spinal cord, spinal column, and the spinal meninges, and their surgical treatment.

These two volumes are profusely illustrated with drawings and plates, many of them coloured, and the work as a whole embodies the author's immense experience in this branch of medicine. All neurologists and neurological surgeons will look forward with pleasure to the appearance of volume iii, "The Brain," and volume iv, "The Sympathetic Nervous System," which will complete Professor Puusepp's monumental contribution to the literature of surgical neuropathology. The publisher is J. G. Kruger, Rütli, 11, Tartu (Dorpat), Esthonia.

"ANNALS OF MEDICAL HISTORY"

The second number of this year's *Annals of Medical History*,² edited by Dr. FRANCIS PACKARD, opens with an article by Sir Humphry Rolleston, being a lecture given under the Chadwick Trust and the Association France-Grande-Bretagne on April 8th, 1932, entitled "The Progress and Pioneers of Preventive Medicine." The cover bears the portrait of W. T. G. Morton, the partner of Horace Wells, and the frontispiece is that of the less famous C. T. Jackson, who claimed to have invented both ether anaesthesia and the electric telegraph. The lives of these and of others, such as Crawford W. Long, who gave ether in 1842, four years before Morton, and S. F. B. Morse, who in 1832 invented the electric telegraph, are sketched by Dr. A. H. Miller in an article on the controversies connected with these inventions. Jackson, who had been a companion of Morse on a forty-days' voyage across the Atlantic, before the invention was published, and the teacher of Morton at the Harvard Medical School, was versatile but unsatisfactory, and spent the last seven years of his controversial life in a lunatic asylum. Captain F. L. Pleadwell, who in 1916 was stimulated by Sir William Osler to go into the activities of "that remarkable philosopher and physician Wells of Charleston," has supplied a life with much information and some previously unpublished letters of the author of the *Essay on Dew*, who, though born in Charleston, spent most of his life in London. In a glimpse of seventeenth century medicine, as gathered from *La medicina difesa* (1699) of A. F. Bertini, professor of medicine at Florence, Dr. Lynn Thorndike packs into less than two pages, supplemented by references and notes covering the same area, a maximum of condensed know-

ledge. What Shakespeare knew about medicine, and especially about mental disorder, is considered at length, with 179 references, the result of much literary research by Dr. Irving I. Edgar. An attractive analysis of the medical wisdom, as shown in his works, of Bret Harte, who became a clerk in a drug store when 19, is made by Dr. L. J. Bragman, and Dr. Jerome Head deals in a similar manner with the medical allusions in *Don Quixote*, which, he says, has contributed an adjective to every language, but is more known than it is read. Dr. Joseph Walsh continues his study of Galen's writings and the influences which inspired them.

PATHOGENESIS OF TUBERCULOSIS

Dr. AUGUSTE LUMIÈRE has written a book entitled *Tuberculosis: Infection—Heredity*³ to show that our current ideas on the pathogenesis and epidemiology of tuberculosis are quite wrong. His main thesis is that the chronic tuberculosis of adolescents and adults is due solely to infection occurring during foetal life with the tubercle bacillus in its acid-fast or in its filterable form. The arguments he brings forward to support this view are many and varied, and some of the weaknesses of our conventional ideas are fully exposed. To contest adequately each of the points he makes would require a book nearly as long as his own. We can merely suggest here that (1) the existence of a filterable, infective, and pathogenic stage in the life-history of the tubercle bacillus has never been satisfactorily demonstrated, and that the most reliable workers in this country, in Germany, and in the United States of America, who have taken the trouble to avoid the numerous technical errors surrounding its so-called demonstration, have failed to obtain evidence of its existence. (2) His attempt to discredit the tuberculin reaction as a specific index of infection is unconvincing: cattle statistics alone show the almost invariable existence of a macroscopically demonstrable tuberculous focus in positively reacting animals. (3) He has failed to account for, or so far as we can see even to mention, the peculiar distribution of the human and bovine types of tubercle bacilli in the cervical, tracheo-bronchial, and mesenteric glands at different ages, which is very difficult to explain on any hypothesis other than that of post-partum infection by the alimentary route with bovine and by the respiratory route with human type bacilli. (4) He affords no explanation of the abolition of tuberculous origin in Toronto as the result of pasteurization of the milk supply.

The word "infection" is used very loosely throughout the book, and indeed it is often impossible to know whether Dr. Lumière is referring to the mere deposition of tubercle bacilli in the tissues, to their latent multiplication, or to their production of frank disease. Without such a definition many of his most arresting statements are meaningless. Great care is taken to call in the aid of statistics to disprove one of our current conceptions—namely, the frequency of conjugal tuberculosis, but the author has carefully avoided subjecting to statistical examination many of the points he wishes to prove himself, such as that tuberculosis occurs in the children of tuberculous parents who are not expectorating tubercle bacilli. The main value of the book lies in showing how very incomplete our knowledge still is of the epidemiology of tuberculosis: its main fault is in arguing logically from unproven and incomplete premisses. It should not be difficult, using the author's method, to prove that measles is inheritable. After all, adults exposed to it rarely contract the disease, and conjugal measles must be very uncommon.

FIRST LINES ON PHYSICAL THERAPY

Nature, M.D.,⁴ by Dr. RICHARD KOVACS, is exactly the type of popular book for which at present there is an acute need. One has only to watch modern sun-bathers at any holiday resort to be aware of the recent widespread recognition of the value of physical methods in the preservation of health. With the increasing application of physical methods in the treatment of disease has come the inevitable exploitation of apparatus by commercial firms. Almost every newspaper displays advertisements of apparatus for self-treatment by so-called "sun" lamps, etc., or has notices of the facilities provided by societies of well-intentioned extremists for all-the-year-round sun-bathing.

The intelligent layman who is anxious for guidance in these matters will welcome Dr. Kovacs's book, which gives an unbiased account, in non-technical language, of the remedial uses of light, heat and water, massage, exercise, and electricity. Emphasizing the fact that any physical measure which is powerful enough to do good is equally likely to be harmful if improperly used, the author issues a warning against the self-prescription of measures which may be dangerous, and describes conditions in which simpler applications are helpful, and may be justifiably self-applied. He gives sufficient emphasis to the fact that competent diagnosis must naturally precede any course of physical treatment.

On reading the chapter on water, those who have hoped for magical cures from medicated baths or spa waters will forgive the author for disillusioning them, because he tells them so honestly what can actually be expected from the different kinds of bath treatments. His discussion of natural and artificial sunlight is especially valuable, and his advice about sun-bathing most opportune—it should prevent much ill-advised and painful burning. The exposure times advocated for American sun-flooded beaches could advantageously be lengthened by bathers in this country. Dr. Kovacs's book should fulfil its purpose admirably in giving the public the information it needs in order to benefit most fully from the renewed interest in physical therapy.

BOOKS ON PAEDIATRICS

Dr. J. POUCEL of Marseilles has written an interesting monograph on Hypertrophic Pyloric Stenosis in Infants⁵ which contains a strong plea for the priority of Frédet as the inventor of pyloroplasty. The general contents of the book are in agreement with the customary teaching in Great Britain, and the insistence upon operation as offering the only chance to severe cases is a good point well made. On one aspect of the subject the author must be criticized: he gives an excellent account of the risks of alkalosis in pyloric stenosis and then in a later section advocates sodium bicarbonate solution for gastric lavage when this is required. This book belongs to Masson's Practical Medicine and Surgery Series.

A recent member of another current French series (Monographs on Paediatrics) is called "Pneumococcal Pleurisy in Childhood,"⁶ by Drs. M. PÉHU and A. Z. ROUGIER. This follows orthodox lines, and is a useful practical guide. The term "parapneumonic" is used for those cases where the empyema occurs simultaneously

with the pneumonia, and is the equivalent of what is now called "synpneumonic" in English-speaking countries.

Another addition to the literature on the diseases of children is *The 1933 Year-Book of Paediatrics*,⁷ edited by Drs. I. A. ABR and A. F. ABR. As in previous years this provides a useful summary of the year's literature, with a sprinkling only of references to work in this country. It is difficult to understand why the recent publications on anaemia by Professor Leonard Parsons and his colleagues, for example, have not been noticed, unless it is that the weekly medical journals are held to contain all the main contributions on paediatrics, there being far more references to these than to the special periodicals, of which the *Archives of Disease in Childhood* is not the least important.

The fourth edition of *Modern Methods of Feeding in Infancy and Childhood*,⁸ by Drs. DONALD PATERSON and J. FOREST SMITH, has also recently been published, and in the preface it is claimed that the principles and practice have been simplified so as to make the book useful to the intelligent mother and "nannie." This being the author's intention we suggest that in the next edition they would do well to devote their first chapter to breast-feeding.

Notes on Books

A Handbook of Psychiatry,⁹ by Dr. JOHN H. EWEN, is intended to present, in a synoptical form, those principles of psychiatry that are of importance at the present time, and to epitomize the more recent knowledge of this branch of medicine. The volume aims at giving as complete an account as possible in small compass of the salient features of the subject of mental disorder, and to this end sections on mental deficiency, the psychoneuroses, and the legal aspect of psychiatry have been included. The author observes that while a synopsis of this kind cannot replace a textbook it can provide a means of rapid revision and a methodical presentation of salient facts. This view would seem to be justified, and no doubt Dr. Ewen's synopsis will be found useful to those who are preparing for a diploma in psychological medicine.

STARCK'S *Volumetric Analysis*¹⁰ is a textbook for students of pharmaceutical, medical, and general chemistry. It is chiefly remarkable for the number and variety of chemical reactions on which as principles are founded the methods described. The subject is treated more from an academical standpoint than from that of the practising analyst. Thus it would seem that an analyst may need to discover for himself in some cases points of detail not mentioned in the text, to which regard must be paid for obtaining trustworthy conclusions. This is not to say that the work is devoid of helpful comment. On the contrary, it contains much important information relating to conditions for which the methods are valid as well as warnings about the effect of disturbing factors. It provides amply for the needs of students, and it affords to those who practise volumetric operations, in work of definitive purpose, a useful and varied choice of principles for application to unusual problems. An appendix giving tabulated directions for qualitative analysis should render the book a useful students' companion.

of the University of Toronto contingent, which went out to Salonika in 1915, is sketched in part, and from a personal point of view, in the letters written by the Professor of Pathology at Toronto to his wife. These letters cover the period up to July, 1916, when Mackenzie returned to England, and, after doing some work with the late Professor T. G. Brodie on the lungs during recovery from chest wounds, took up again his teaching for the winter session at Toronto. Unfortunately he had, while in the East, picked up an infection which eventually led to his death in 1922, at the age of 57, from endocarditis. His devoted wife gives an intimate and graphic account of a very interesting personality. Of pure and distinguished Scottish stock, he was originally a biologist, and while bacteriologist to the Provincial Board of Health proceeded to the degree of M.B. at Toronto in 1889, and in the following year was appointed professor of pathology and bacteriology in his own university. There is a resemblance between the early training of Mackenzie and of the late Professor J. G. Adami, whose life was also written by his wife in 1930, and who held the corresponding chair at McGill, Montreal, from 1892 until the outbreak of war took them both to Europe. They both took a very broad view of pathology as a branch of biology, and organized their departments at a time when their chairs became whole-time appointments. Mackenzie was devoted to research, but temperamentally was very cautious in publishing his results, and, like Adami, was versatile and had many outside interests, especially artistic.

*The Students' Pocket Prescriber*¹² has now reached its tenth edition, having been published first in 1882. The editor, Dr. D. M. MACDONALD, is to be congratulated on the long life of this little work. The present edition has been revised throughout in accordance with the changes introduced by the *British Pharmacopoeia*, 1932. The volume contains a large amount of varied information, the most important feature being a list of nearly 600 different prescriptions. On the whole these prescriptions follow the classical tradition rather than the modern movement towards simplicity.

Preparations and Appliances

CERVICAL FORCEPS AND CLAMP FOR TUBAL INSUFFLATION

Mr. F. NEON REYNOLDS, F.R.C.S.Ed. (London, W.), writes:

The instrument illustrated was devised to facilitate the operation of insufflating the Fallopian tubes. It consists of two pairs of vulsellum forceps connected by a telescopic cross-piece, carrying a quick-thread clamp for holding the uterine cannula. Each vulsellum is provided with a cup-and-ball mounting connecting it to the cross-piece, thus allowing

completely free and individual movement in any direction. By this means the cervix can be seized in any place or position which may be required to close the cervical canal tightly round the uterine tube.

The methods of use are as follows:

1. When using a Provis uterine cannula, or any other of similar pattern, the forceps are taken apart, and the one not carrying the clamp is fixed to the anterior lip, the other to the posterior lip. After this the forceps are reconnected. The uterine cannula is passed into the cervical canal, and its

stem placed between the disks of the clamp. The cannula is now pressed firmly into the cervix with sufficient pressure to block the canal, and, while pressure is still maintained, the clamp is tightened up. The complete unit of forceps and cannula can now be left fixed in position without being held. This leaves the hands of the surgeon free to manipulate the insufflator or auscultate the abdomen, should he so desire.

2. When using a uterine cannula of Forsdike's pattern, or in the case of a patulous or torn cervix, it is necessary to adjust the grip on the cervix in order to close the canal round the cannula before fixing the cannula in the clamp. In such cases each vulsellum can, if required, be turned over in order to obtain a side-to-side grip of the cervix to give a satisfactory closure of the canal.

The instrument was made for me by Messrs. Allen and Hanburys, Ltd.

A NEPHRECTOMY CLAMP

Mr. W. K. IRWIN, F.R.C.S. (London, W.), writes:

In the operation of nephrectomy I have sometimes found that the clamp slipped off the pedicle after the kidney had been removed. With a view to avoiding this accident, which may be serious, I have designed the instrument shown in the accompanying illustration. It is made somewhat on the

pattern of Thomson-Walker's renal pedicle forceps. The crushing surfaces of the instrument bear chevron-like serrations, which grip the part firmly, and at the same time tend to prevent transverse spreading of the pedicle. The jaws are three inches long and the shanks six and a half inches long.

The clamp has been made in accordance with my suggestions by Messrs. Down Bros., St. Thomas's Street, S.E.1.

AMERTAN

Amertan (Eli Lilly and Co., 2, Dean Street, W.1) is a jelly for the treatment of burns. It contains 5 per cent. tannic acid and one part in 5,000 of merthiolate. The latter is a new organic mercurial germicide. The value of the tannic acid treatment of burns is now fully established, but various writers have pointed out the desirability of combining antiseptic treatment with the tannic acid treatment, and this preparation provides the combined action. The manufacturers supply a useful brochure which gives a short and clear account of the principles of tannic acid treatment of burns and full details regarding the proper method of employing amertan.

AMYTAL

Amytal (Eli Lilly and Co.) is the proprietary name for isoamylethyl barbituric acid, a compound that has been synthesized and investigated in the Lilly Research Laboratories. The sodium salt of this compound has been extensively used as an intravenous anaesthetic in animals and also for human surgical anaesthesia. The experience thus obtained has shown that the drug has a relatively wide margin of safety and has little tendency to produce toxic side-effects. The manufacturers recommend it as a hypnotic in insomnia and as a soporific and sedative. The hypnotic dose recommended is from 1½ to 6 grains.

EXTRALIN

Pulvules extralin (Eli Lilly and Co.) contain a liver-stomach concentrate for use in pernicious anaemia. The discovery of the value of liver feeding in pernicious anaemia led to an extensive search for potent liver concentrates. It was next discovered that human gastric juice acting on meat produced a substance which has a similar action to liver or liver concentrates. Investigations in the Lilly Research Laboratories showed that the potency of liver or liver extracts could be greatly increased by digestion with stomach tissue. Extralin has been prepared by the last-mentioned method, and has a potency per unit weight about three times that of potent liver extracts. The preparation is standardized by clinical tests on cases of pernicious anaemia. The daily dose recommended is 6 grams (twelve pulvules), and this has an action equivalent to 250 grams of raw liver.

CHEMICAL TRANSMISSION OF NERVE IMPULSE

In his Linacre Lecture, which we print in the current issue of the *Journal* (p. 835), on the chemical transmission of the effects of nerve impulses, Sir Henry Dale has given a concise history of certain new conceptions that are changing our ideas on some of the most fundamental subjects in physiology and pharmacology. The behaviour of the nerve-muscle preparation of the frog and that of the specific nerve endings of the autonomic nervous system have been worked out exhaustively, and these studies have themselves led to great and important developments in both physiology and pharmacology. The theories held as to the mode of activity of these two systems would seem to stand on a most solid basis; yet they are now being ruthlessly attacked, with no respect for their antiquity or for the fact that upon them so much has been built.

The change of electric potential in nerves and muscles that accompanies excitation was one of the first physiological problems to be subjected to accurate quantitative analysis, and the results thus obtained suggested that the transmission of the excitation from nerve to muscle was a purely physical process. During the present century, however, evidence has accumulated which indicates that nerve stimulation liberates minute quantities of chemical substances around the nerve endings, and that this causes excitation or inhibition of the structures which the nerves supply. This hypothesis was first advanced in 1904 to account for the mode of action of the sympathetic system, but it was not until 1921 that definite experimental evidence for the theory was brought forward by Loewi. He first showed that the effects on the frog's heart of vagal stimulation were due to liberation of acetylcholine, and those of sympathetic stimulation to the liberation of adrenaline. Subsequent research established these facts in regard to the action of autonomic nerves on a wide variety of glands and muscles. All this work dealt with the endings of non-medullated, post-ganglionic nerves, but during the last few years further evidence has gone to show that the medullated motor nerve endings function in a similar manner and also set free acetylcholine: it also appears probable that an identical change takes place at the central endings of sensory nerves.

The general trend of this work, some of which is only a few months old, is summarized by Sir Henry Dale in the following sentences: "In any case, the evidence, even so far as it has been obtained, seems to give promise that we may soon be able to complete

the picture of the transfer of excitation, at all cyto-neural junctions in connexion with the peripheral nervous system, by the liberation of chemical transmitters"; and "We get an impression of the cholinergic mechanism as having the more general application in the functions of the nervous system, and probably an earlier origin in evolution, and of the adrenergic mechanism as a more specialized and probably a more recent development." These conclusions are of the greater interest because the lecturer himself is responsible for no small part of the work on which the new theories are based. The whole subject is at present in the course of extremely rapid development, and hence many of the conclusions must be regarded as provisional. The new conceptions, as we have said, imply a drastic revision of ideas about many of the fundamentals of physiology and pharmacology. At present they do not appear to have any immediate clinical application, but past experience teaches that any important advance in basic theories leads sooner or later to an amplification of our powers to combat disease.

THE COMPOSITION OF FOOD

The grave abuses in the adulteration of food which were brought to the light of day by a Select Committee in 1855 prompted remedial legislation which was largely ineffective until the passing of the comprehensive Sale of Food and Drugs Act in 1875. The Public Health (Regulations as to Food) Act of 1907 empowered the central health department to condescend upon more detailed protective measures, and finally in 1928 the Food and Drugs (Adulteration) Act consolidated the previous legislation. At the present time a limited number of foods are defined by statute or regulation, the legitimate sources and composition of certain others are laid down, and the addition to foods in general of preservative substances and colouring matters is precisely controlled. Now the Departmental Committee on the Composition and Description of Food, in its report just issued,¹ expresses the view that it is desirable that the law should be altered so as to enable definitions or standards to be prescribed, or declarations of composition to be required, for articles of food other than liquid milk.

Enactments along these lines are in operation in foreign countries and in some of the British Dominions. In the South African Union fifty articles of food, and in Canada 150, are defined and standardized. The witnesses whom the committee called were in general favourable to changes in the law of England, though they revealed diversity of opinion as to the scope of any new measures. Strong evidence was led in opposition to the use of misleading descriptions, and in support of the declaration of the composition of infant and

¹ Report of the Departmental Committee on the Composition and Description of Food. 1934. Cmd. 4504. H.M. Stationery Office. (21. net.)

diabetic foods. The members of the Departmental Committee themselves, while answering as above the question put to them in their terms of reference, consider that the case for the extension of standards to all articles of food is not made out. They think that in a large number of cases the housewife, when she makes her purchase, does now get an article which, in terms of the Food and Drugs (Adulteration) Act, is of the nature, substance, and quality she asked for, and that she would not be a scrap better off for a multitude of standards or declarations of composition. In other instances, standards and declarations are necessary for the protection of the consumer. Nevertheless, while it is right that the public, when buying, should know what they are getting, elasticity must be allowed in the preparation of many articles, and in any event it is obviously useless to prescribe requirements conformity to which cannot be checked by chemical analysis or other accurate means. Flavour, for example, cannot be standardized, and of the merit of some commodities the purchaser himself is probably the best judge.

The committee thinks it important, as various witnesses maintained, that people buying infant and invalid foods should know what these contain. For sweetmeats as a group declarations of composition are not essential. Though toffee now, as it seems, is no longer usually made from butter, the purchasers of it appear still to be getting what they want as in days gone by. The committee takes a serious view of the misleading nature of some food advertisements and food labels. It agrees with the strong opinions expressed on the point by some of the witnesses, and it adopts a recommendation advanced by the Food Manufacturers' Federation that claims made in advertisements should be deemed to be part of the package label. It thinks, too, that in the retailing of pre-packed articles the law should afford the retailer more protection against the risk of prosecution than it does at present. While the committee does not suggest the formation of a Standing Advisory Committee having for its sole concern the administration of the Food and Drugs Acts, as had been suggested by the Society of Public Analysts in the event of all articles of food being made subject to regulation, it entirely agrees that no new standards should be laid down without giving to manufacturers and all others concerned the fullest opportunity of submitting their views on any proposal, and it thinks that where there is wide divergence between the parties interested the matter should be referred to a committee of three independent persons, who would hear evidence and report their findings to the Minister of Health.

The whole report of the Departmental Committee is moderate in tone, and its suggestions are reasonable alike in scope and substance. The recommendations put forward, if given effect to, should add to the efficiency of food control with a minimum of disturbance to current arrangements, which, it is generally admitted, have hitherto usefully served the public interest.

MENTALLY ABNORMAL DELINQUENTS

The problem of the prisoner with a slight degree of mental disorder or deficiency is one of the most troublesome with which the prison medical officer is confronted. Dr. W. Norwood East, one of H.M. Commissioners of Prisons, writes in their report for 1932¹ that magistrates do not always deal as they should with mentally abnormal prisoners. The general practice, as he says, is that when the Bench suspects that an accused person's mental condition is not normal he is remanded for inquiry, and a medical report is submitted to the court at the second hearing. Certain courts, however, says Dr. East, sentence an offender to imprisonment even when they have reason to believe that he is defective or insane. For example, a man was sentenced to three months' hard labour for indecent exposure, and the magistrates expressed a wish that the prison medical officer should keep him under observation with a view to his certification as a mental defective. However beneficial such a sentence might have been for the protection of the community, a short remand while arrangements were being made to admit him to an institution would have been no less protective to the public and fairer to the prisoner. This particular man, says Dr. East, was not defective; he would therefore have been sentenced in the ordinary way on the second hearing.

Although in certain cases a prison may be the only place in which to detain a defective who is a public danger, it is not usually necessary to sentence to imprisonment a defective charged with a minor offence. Dr. East quotes a case in which the Bench sentenced an old man to seven days' imprisonment for begging, in spite of the report from an experienced medical officer that he was insane; the man was certified from prison. Moreover, magistrates sometimes sentence an offender to imprisonment asking that he may be kept under observation during the currency of the sentence so that the court may be informed of his mental condition before he is released. Although, legally speaking, a prisoner is amenable to trial and conviction whatever his mental state, provided he is fit to plead and knew what he was doing when he committed the crime, Dr. East rightly points out that informed opinion to-day expects a court to consider the mental condition of the offender before it sentences him. The court cannot do this unless it knows the mental condition of the prisoner before it passes sentence. There are, he says, three groups of convicted prisoners: those whose mental condition is (a) normal, (b) abnormal but uncertifiable, and (c) certifiable. Obviously the placing of members of the first group under mental observation should be avoided whenever possible. In the second group, although the medical officer may not be able to help the court, the court should none the less be informed of relevant medical facts. Offenders in the third group should only be imprisoned if their safety

¹ Cmd. 4553. Report of the Commissioners of Prisons and the Directors of Convict Prisons for the Year 1932. London: H.M. Stationery Office. 1934. (1s. 6d. net.)

or that of society demands it. Some courts, when asking that a prisoner be kept under observation, furnish no information to help the medical officer. Naturally, the more the doctor knows about the case the better, and Dr. East commends the practice of one important court of sending the prison medical officer information on the printed request form. The difficulties on both sides are very great. Magistrates are busy, and a treatment which is desirable from the medical point of view may be impracticable or wrong from the point of view of the law. On the other hand, the prison medical officer is always up against the problem of deciding whether the mental inefficiency of a given prisoner is due to mental deficiency in the sense of the statute, which requires that the condition shall have existed before the age of 18 years.

The question of how far inefficiency is due to mental defect is a very difficult one, and part of the even wider question of the whole relation between mental abnormality and crime. A better treatment of delinquents will only be achieved as magistrates come to appreciate more clearly the medical implications of their task, and as psychiatrists become more familiar with the legal system which the courts have to administer. This approach from both sides is being assisted to a large extent by the Medico-Legal Society, but this country is exceptionally backward in its appreciation of the essential partnership of the doctor and the lawyer. Only when a medico-legal institute is established in London will this problem and other similar ones be on the way to solution.

OXYGEN THERAPY FOR INFANTS

The respiratory difficulties of the newborn, and especially of the premature infant, present a problem in therapeutics which has not yet been satisfactorily solved. A recent report¹ suggests that oxygen therapy is of value, and Dr. W. M. Boothby of the Mayo Clinic has described a modification of the Hess incubator, using it as a miniature oxygen chamber. He points out the three fundamental principles on which modern investigations on the structure of oxygen tents and the like have been based: continuous administration of a constant concentration of oxygen within narrow limits of variation, accurate knowledge of such concentration, and reasonable cost as regards both the structure and its operation. The standard Hess incubator, according to the present plan, is converted into a miniature oxygen chamber mainly by arranging an airtight top, fitting into a trough to make a water seal. Oxygen is supplied from a large cylinder through a flow-meter, and the aim is to keep this gas at a concentration of 50 per cent. In the present apparatus this is achieved by a flow of about 12 litres per minute for two and a half to three and a half minutes, and thereafter at a rate of 1 to 2 litres per minute. For very small infants this rate of flow suffices to prevent undue accumulation of carbon dioxide and keeps the humidity from rising too high. The temperature of the incubator is kept at the desired level by the same

electrical mechanism as when ordinarily used. The running expenses are estimated at four dollars a day, and the initial cost of conversion is not high. A simple form of gas analysis apparatus is an essential feature of the converted incubator, and it is claimed that an intelligent nurse can learn to use this in two afternoons. Dr. Samuel Amberg, in commenting² upon the new apparatus, points out the vulnerability of premature infants to disturbances causing anoxaemia; and, because such respiratory difficulties may come on at any time, infants below a certain weight in the paediatric section of the Mayo Clinic are now placed immediately in the oxygen incubator, where they remain for two weeks to a month. He considers that, although the number of infants so far treated has been small, the results have justified the title of "life-saving" for the apparatus. It has also proved of value when, for one reason or another, infants who were not premature needed oxygen. An example of this is quoted by this author in a further communication,³ where he describes the use of oxygen therapy for a 7-weeks-old infant who was having severe attacks of whooping-cough and cyanosis, really to aid the latter. To his surprise this stopped the attacks of coughing and moderated the course of the disease. For older children, given through a suitable mask, oxygen was found to be effective in stopping a given paroxysm or set of paroxysms, though not, of course, curing the disease. Oxygen alone appears to be much more effective than carbon dioxide alone, and is apparently the beneficial element of carbon dioxide and oxygen mixtures when used for whooping-cough.

THE FATHER OF BRITISH DERMATOLOGY

Dr. H. Haldin-Davis has contributed an interesting article on Robert Willan to the *British Journal of Dermatology and Syphilis*.⁴ Dr. Willan was a Quaker physician born near Sedburgh, in Yorkshire, in 1757. He settled for a time at Darlington and moved afterwards to London, where he gained a large practice in Bloomsbury Square. Phthisis and tabes mesenterica led him to Madeira, where he died in 1812, after living in the island for two years. Willan was the first in this country to make a satisfactory nomenclature of diseases of the skin, and for it he was awarded the Fothergillian gold medal of the Medical Society of London in 1780. He is remembered as a physician, but little was known of him as an individual. Good fortune led Dr. Haldin-Davis to make the acquaintance of Miss Mary E. C. Howell, the last surviving descendant of Dr. Willan. From her he has obtained eleven letters, some written by Willan himself, some by the hand of his wife, and one by his son. She has also drawn his attention to three portraits of Willan: one she gave to the school at Sedburgh, one to the Royal College of Physicians of London, and one to the Medical Society. Dr. Haldin-Davis has also secured a copy of Willan's bookplate, his medicine chest, and a rubbing from his tombstone in the British cemetery at Madeira. For the last he thanks the Rev. W. Graham, the English chaplain, and the veteran Dr. Michael Grabham, to whom Madeira owes much. The memorial has long since been removed from the actual grave, the exact position of which is

¹ *Proceedings Staff Meetings Mayo Clinic*, February 28th, 1934, p. 122.

³ *Lancet*, 1933, p. 133.

⁴ 1933, *ibid.* 493.

unknown, and it now stands one of a row of similarly displaced tombstones. Dr. Haldin-Davis entitles his communication "Some Personal Relics of Robert Willan." He deserves thanks for the collection and preservation of these relics of a physician about whom comparatively little was known in spite of the good work he accomplished.

INCOME TAX AND WHOLE-TIME APPOINTMENTS

A member has called attention to the hardship arising out of the fact that though the subscriptions payable to the British Medical Association, and to medical defence societies can be treated as allowable deductions for tax purposes by members in general practice, such deductions are refused in the case of individuals assessed for salaries received from hospitals, public authorities, etc. The equity of the claim is nearly, if not quite, the same in each case, and the difference lies in the application of the statutory rules. The leading case on the point was decided in 1925, and is quoted as *Simpson v. Tate*.¹ The facts were that Dr. Tate, a county medical officer, claimed to deduct his subscriptions to certain professional societies, and it was admitted that it was not a condition of his employment that he should be a member of those societies, though such membership was customary for county medical officers. Mr. Justice Rowlatt pointed out that to be allowable the payments must be brought within the rule of Schedule E, which restricts the deductions to expenses wholly, necessarily, and exclusively incurred in the performance of the duties of the office, and gave a very decided opinion against granting the allowance. He said: "This gentleman . . . is continually keeping himself qualified very properly and rightly by keeping himself abreast of all the highest developments and knowledge of the day. But when one looks at it closely one sees that that is not in the performance of duties. . . . I think that all subscriptions to professional societies and all taking in of professional literature and all that sort of expense . . . are things which can none of them be allowed." The case was fully argued: Mr. Justice Rowlatt was a judge of special eminence on income tax questions, and it may be assumed that his decision could not be upset by further action in the courts; in any event, a case would have to be taken to the Court of Appeal, because the *Simpson v. Tate* decision would almost certainly be regarded as binding in the Divisional Court. As a result we are left with the difference between the greater leniency of the Schedule D rule applied to a general practitioner and the greater strictness of the Schedule E rule as judicially interpreted. Of course, if appointing bodies would make it a condition that their medical officers should belong to the B.M.A., then those officers could legally deduct the amount of their subscriptions, but it may be doubted whether many bodies could be induced to pass the necessary resolutions. Coming to appointments more subject to medical control it may be assumed that while most mental hospital boards would desire their medical officers to be members of the Royal Medico-Psychological Association, they might nevertheless feel some hesitation in making such membership a necessary condition of employment. The case of lecturers and

teachers is perhaps not clearly covered by the *Simpson v. Tate* judgement, but is in some respects similar to that of M.O.'s, and a test decision would, we fear, prove unfavourable, even if the initial difficulty of raising the legal costs could be overcome. Many years ago this distinction between the Schedule D and the Schedule E rules was more irritating, because it was of wider application; but the acceptance by the Board of Inland Revenue of the convenient practice of including the income from minor medical appointments with the general earnings has enabled most practitioners to escape from the application of the narrow and restrictive Schedule E rules. For the whole-time medical officer, or official, however, there is no escape, and there seems no available means at present of avoiding the hardship, unless the appointing authority chooses to pass a resolution requiring membership on the part of its officers. We must admit that it is difficult to frame rules for a tax of such widespread incidence as the income tax which shall avoid creating a justified sense of inequity; yet the indirect value of the work of professional societies to those for whose well-being the medical officer is responsible needs no emphasis, and though the amount of the subscriptions paid by any one individual may not be large, the high rate of tax makes the hardship distinctly perceptible.

A LOCAL GOVERNMENT ENCYCLOPAEDIA

The *Municipal Year Book*¹ has now become an amazing compilation. From a modest volume of less than four hundred pages it has grown until in the current edition it contains 1,527. There can scarcely be a volume of its kind which gives more complete and accurate information concerning the field it covers. The claim that it is "an authoritative survey and a permanent record of the principal events in connexion with local government during a memorable year" is entirely justified. It is up to date in every respect, except that, as it was not possible to delay publication in order to include the results of the triennial elections of county councils in March last, these have been printed as a special Supplement, and will be sent gratis to every purchaser of the *Year Book* who asks for it. Not only does the volume contain a large amount of information about every local authority in England and Wales, Scotland, Northern Ireland, and the Irish Free State, but in almost all cases it gives a complete list of members and officials of these authorities, whether counties, municipalities, urban or rural districts, or joint authorities of various kinds, such as those for hospitals, for port sanitation, and for sewerage and water. Its interest and usefulness are by no means confined to its function as a work of reference for names and statistics, indispensable as this is. There are equally valuable surveys and articles dealing with many aspects of education, of health work of all sorts, of housing and slum clearance, of libraries, museums, and art galleries, of public assistance, and indeed of every department of local government activity. There is a legal section reviewing the relevant law cases of the year, and one dealing with recent Acts of Parliament, Statutory Orders, and Regulations. There is even a summary of the report and findings of the Departmental

¹ *The Municipal Year Book, 1934*. Edited by James Forbes. London: The Municipal Journal Ltd. (30s. net.)

Committee on Sterilization. To all those who are interested in local administration, whether in the sphere of health, education, public assistance, or other work, and whether actively engaged in such administration or no, possession of this book, or at least ready access to it for consultation, would seem almost essential. To have produced it is a wonderful achievement.

THE COST OF HOSPITAL BUILDING

The Royal Institute of British Architects has just published a report on the cost of hospital building which was prepared by a special committee appointed by the institute to submit evidence to the Ministry of Health Departmental Committee on the Cost of Hospitals and Public Buildings. The R.I.B.A. committee was composed of five members of the architectural profession, each of whom has had long and wide experience in the design of hospitals, and of one Fellow of the Chartered Surveyors' Institution. The report, a pamphlet of thirty-one pages, is concerned primarily with non-teaching general hospitals, but it will be found that many of the incidental recommendations made by the committee apply equally well to teaching, mental, and specialist hospitals. After a general discussion of standardization in hospital design the committee formulates a basis on which a true comparison of costs can be made, and then deals briefly with special forms of construction. A large part of the middle of the report is given to a consideration of the most economical disposition of buildings on a site and of departments within a building scheme. The whole document will prove of interest and value to everyone concerned with the planning and construction of hospitals. It can be obtained from the R.I.B.A., 9, Conduit Street, W.1, for 1s. 6d. (post free).

THE ACADEMIC ASSISTANCE COUNCIL

We print elsewhere a summary of the first annual report of the Academic Assistance Council, formed a year ago to help those university teachers and investigators "who, on grounds of religion, political opinion, or race were unable to carry on their work in their own country." The record of work done is creditable. From the funds raised by the council itself, forty-nine scholars and men of science have been provided with means to continue their work for a year, and, through other agencies, maintenance grants for ninety more displaced university teachers have been found. Extracts from reports made on the work of some of these men and women show that the scientific work being done by them is of the highest quality. Unfortunately, the need which led to the formation of the council is not less than a year ago; it may be greater, and, unless further financial assistance is available, even those now being helped cannot be helped further. The council has construed its obligations strictly: those whom it has helped have been scholars and scientific workers whose labours were of benefit to the whole world. There may be—indeed, there must be—differences of opinion as to the desirability or practicability of encouraging medical or other professional men to settle in countries where the supply of qualified persons is adequate. There can be no difference of opinion as to the folly of letting exceptional ability in the field of

research run to waste. The Academic Assistance Council should therefore command the support of all who value learning and research, and view with dismay the waning of intellectual freedom in so many parts of the world.

CONFERENCE OF VOLUNTARY HOSPITALS

A conference of the voluntary hospitals of Great Britain and Ireland, organized jointly by the British Hospitals Association and the Incorporated Association of Hospital Officers, will be held in London from June 13th to 16th. The formal opening on Wednesday, June 13th, at 10 a.m. by the Prince of Wales in the Council Chamber of the Guildhall will be followed by discussions on voluntary hospitals, past, present, and future, and on out-patient departments. On the morning of June 14th, in the Goldsmiths' Hall, the functions of the cottage hospital, and the hospital and its architect will be discussed; and on June 15th, in the Merchant Taylors' Hall, hospital administration on the Continent, and co-operation between voluntary and municipal hospital services. On the last morning the annual meeting of the British Hospitals Association will be held in the Clothworkers' Hall, followed by a discussion on some aspects of almoners' work. The Duke of York will preside at the annual dinner in the Guildhall on June 14th, and each afternoon will be devoted to visits to hospitals and other institutions.

A CLINICAL RESEARCH UNIT

The Middlesex Hospital has just received from Mr. S. A. Courtauld a gift of £15,000 to found a clinical research unit, under direction of the medical school council, for the intensive and exclusive investigation of such diseases as may from time to time be selected. The unit will consist of small wards of one to three beds—in all, fifteen to twenty beds—a clinical lecture theatre, test rooms, and other offices, under the control of the heads of the Institute of Pathology, the Courtauld Institute of Biochemistry, and the Department of Physiology, in collaboration with members of the medical staff particularly interested in the diseases or conditions upon which it may be decided to concentrate the scientific resources of the hospital, medical school, and research laboratories. Mr. Courtauld's gift of £15,000 to found a clinical research unit adds one more to his large benefactions to the Middlesex Hospital Medical School. It is without precedent in this country for a medical school to be given direct access to, and (under the ultimate responsibility of the Board of Management for its patients) a large measure of control over, beds in the associated hospital. By this means the professorial staff will have more immediate contact with patients and their illnesses, and it is hoped that the fruits of laboratory work will be carried even more quickly into the wards. Patients, too, in this unit will have the advantage of a stay prolonged, when advisable, far beyond what is possible in the general wards.

The annual oration before the Medical Society of London will be delivered by Professor George E. Gask, on "Clean Wounds, Ancient and Modern," at 11, Chandos Street, W., on Monday, May 14th, at 5.30 p.m.

CERTAIN MEDICO-LEGAL DIFFICULTIES CONCERNING OCCUPATIONAL DERMATITIS

BY

P. B. MUMFORD, M.D., F.R.C.P.

HONORARY DERMATOLOGIST, MANCHESTER ROYAL INFIRMARY;
HONORARY ASSISTANT PHYSICIAN, MANCHESTER AND
SULFORD SKIN HOSPITAL

The following points are put forward, at the suggestion of a medical referee, in the hope that they express fairly some of the difficulties and anomalies regarding occupational dermatitis, its diagnosis, and certification. Such difficulties are equally realized by the general practitioner, the employer and his insurance company, by the employee and his union, by the dermatologist who investigates and reports, and finally by the medical referee who is called in to the disputed cases.

THE WORD "DERMATITIS"

To one who has been concerned in many types of dermatological problems in connexion with the Workmen's Compensation Act it appears a deplorable fact that the name "occupational dermatitis" has by usage and familiarity frequently been replaced by the name "dermatitis." One frequently hears of, and reads, certificates to the effect that the sufferer is affected with dermatitis. The writer has even been asked by a county court judge, "Will you please tell me whether this man has, or has not, dermatitis." The employment of the unqualified noun causes much confusion in the lay mind and in the unspecialized medical mind. The exact interpretation of the word "dermatitis" is not clear even to dermatologists, who have a varied conception as to its limitations. In "compensation" circles the word has acquired an almost unholy significance, and often implies, without comment, that a sufferer from dermatitis is one who has a skin inflamed as a direct result of, or accelerated and/or aggravated by, occupation (the all-inclusive "dust or liquid"). Attempts to prove in the witness-box that "dermatitis" is an extremely loose word, of no watertight definition, and a word which might rationally be applied to every disease of the skin would only lead to worse confusion. It must be agreed that the etymologically correct interpretation of the word is "an inflammation of the skin." Such inflammation may be internal or external in origin: it may be brought about equally by the toxins of scarlet fever as by exposure to chemical irritants.

Further, to define exactly as to what should be included in the phrase "occupational dermatitis" is no easy matter. There can be no question as to the correct inclusion of such conditions as "dye-workers' dermatitis" in which synthetic dyes cause direct irritation of the epithelium. But an opinion as to the share of blame to be allocated to a recognized irritant in an individual case is but rarely easy.

INTERPRETATION IN CERTAIN CASES

As a concrete example one may consider a mackintosh worker of 60 years of age and thirty years of uninterrupted employment, who has been accustomed to apply rubber solution with his fingers in the making up of garments without skin injury. For no apparent reason he develops an eruption on his fingers, which proves easy to cure by simple protectives as long as the man remains away from work. The rash reappears within a few days of his resuming his previously innocuous occupation. One can place three interpretations at least upon these facts: (1) The individual has developed a chemical substance in his skin which reacts with explosive force to a primary external irritant with which he comes into contact—that is, a specific sensitization has occurred. (2) Many years of exposure may have brought about some change in the physical character of the cells of the skin or in the activity or nature of the local skin secretions. Such

change or changes have resulted in an impaired resistance to many different and non-specific external agents. These agents were not irritants prior to the local changes. (3) The changes mentioned in this last interpretation may have resulted from inherent metabolic, endocrine, or senile changes in the individual, apart from previous exposure. They have brought about, however, an exactly analogous lack of skin resistance.

The first interpretation on any given case should rightly permit compensation, but not always the latter two. It would, however, be a capable witness who could differentiate conclusively between the three concepts to the satisfaction of either lay or medical jurisdiction. Distinction between the first two groups is of importance, since the degree of compensation is involved. In Group 1 specific sensitization results in the man relinquishing one particular occupation. In Group 2 non-specific irritability precludes the worker from a very large number of different occupations, since there are very few, if any, occupations of manual type which do not involve the use of substances reported as having acted as irritants.

To exemplify these different groups. A confectioner called upon to mix pastry by hand may develop an unusual superficial response to flour proteins—such an individual could be safely employed later in any trade other than baking and confectionery. If, however, the dermatitis from which he has suffered has been due to prolonged exposure to water, to soap, and to friction, and his skin has become locally unstable, the individual would be precluded equally from work as a car cleaner, as a dye-worker, a coach painter, or a cement-worker. This local instability of skin implies development in the skin of some single antigen which is produced with equal facility by widely varying mechanical and chemical irritants. Such antigen, blood-borne, may act as an irritant to the skin of other areas of the body.

INDIVIDUAL SKIN REACTIONS

A further anomaly in the interpretation of "occupational dermatitis" lies in the varying types of skin to be found in the apparently healthy. Not only does the human skin vary from individual to individual in its physical characteristics, but it varies widely in its response to chemical irritants. Certain concentrations of simple substances, such as picric acid and perchloride of mercury, act injuriously on every skin—lesser concentrations irritate fewer, and some affect only a very small percentage. These groups are clearly more likely to develop skin trouble. Certain skins are unable to withstand excessive washing after work in which dust or oil is encountered. The writer calls to mind a case of recurrent "occupational dermatitis" cured by marriage. The naive explanation given by the sufferer was that he did not need to wash so vigorously now that he had "finished courting." Employers are at present called upon to accept full responsibility for a departure from the normal which is an inherent and not an acquired change. A reversal of this opinion is unlikely, since the law reads that acceleration or aggravation by work of a disease entitles the workman to compensation.

Considerable difficulty and liability for divergence of medical evidence results from (1) cases of general out breaks which occur after exposure to local irritant; (2) cases in which relapses occur in the absence of exposure to the original supposed irritant. A working, but admittedly hypothetical, theory as to aetiology lies in the conception above mentioned that a non-specific antigen may be developed by the skin in response to various primary irritants. An example of this conception would be found in the case of a gardener who develops acute dermatitis of the hands from sensitization to primula. Such dermatitis may be followed in a varying period by a morphologically similar general outbreak on the trunk and limbs, areas not directly exposed to the primary antigen. This would appear to be the result of the production of some substance derived from damaged skin on the hands. Improper treatment of the original areas will almost invariably produce an exacerbation of the distant areas of inflammation. As a natural sequence to

this the sufferer may develop a similar widespread eruption to other locally applied irritants, even soap and water at later dates. The cutis as a whole is sensitized to products of damaged epithelium on the hands. Are such cases to be regarded as "occupational" in all subsequent outbreaks, or is the individual suffering from a condition of unknown aetiology which was provoked on the first occasion by a substance encountered at work, but which might equally well have been produced by a dietetic indiscretion or a severe infection of the scalp? Is the original spark responsible for every subsequent conflagration on the grounds that it has rendered a hitherto non-inflammable substance explosive, or was that substance explosive previously?

LEGAL ASPECTS OF DERMATITIS

Some criticism may perhaps be made regarding the methods by which cases come under notice, and the legal processes therein concerned. A simple example of possible injustice would be the following.

A baker develops an outbreak of dermatitis. The dermatitis may affect his hands and face, and may be of almost any aetiology. The man hears of a workmate who had "occupational dermatitis" and sees the factory surgeon. If he does not do so his panel practitioner, on stopping the man from work, gives a certificate stating non-committally—"dermatitis or eczema." The man's union, noting his occupation, naturally fails to differentiate between *post hoc* and *propter hoc*, and refers him to the factory surgeon. The latter, grossly underpaid for a detailed examination and investigation, may fail to realize the wide difference between "eczema in a baker" and "baker's eczema," and grants a certificate. Yet the eruption may equally be due to a week-end in the man's potting shed handling primula or fertilizer. After a case is reported the insurance company usually refers the man for an opinion to a dermatologist. He will often first see the case many weeks after onset, and is discouraged from approaching the man's own medical attendant, and still more from questioning the factory surgeon. The form of certification contains no detail of any help, and usually consists of names, addresses, and initials placed against the phrase "dust or liquids."

Should the dermatological opinion differ from that of the factory surgeon the case is referred to a medical referee. This last is usually a widely experienced and conscientious general medical consultant, who is asked to adjudicate in a large number of different types of cases, varying from minor "nystagmus to silicosis." He can hardly be expected to have an intimate knowledge of the many rarities and difficulties over which the dermatologist himself is often puzzled, and yet his opinion is final, even in the absence of the documentary detailed reports which the two opposite opinions have made. There does not appear to be any method by which he can openly discuss the case and its problems with the other medical men involved.

The after results of acceptance of liability are again often confusing. As a matter of practice it is almost impossible to deal fairly towards an individual who has had an accepted "occupational dermatitis," but who continues to develop further attacks of skin inflammation years after the original attack, and frequently years after exposure to the supposed cause.

THE REMEDY: A DERMATOLOGIST PANEL

The remedy for some of the above anomalies is perhaps Utopian. It is suggested that a case of suspected "occupational dermatitis" is referred by the certifying factory surgeon without definite decision to one of a panel of dermatologists. The latter should be asked to decide by means of "patch" and other tests as to whether the eruption in question is a specific eruption associated with work, or is a constitutional eczematous manifestation. The Workmen's Compensation Act makes no direct reference to the important question of idiosyncrasy nor to the question of constitutional eruptions provoked by work. Re-wording the phrase "long and continued exposure"

with definition as to time might be helpful. The point at issue would appear to be: "Would this man have developed a skin eruption whatever his occupation, or is the long and continued exposure the causative factor?"

Decisions of this nature can only be attempted by a dermatologist, and perhaps the above suggestions of a "dermatologist panel" for each circuit would be helpful. As an alternative procedure, an adequately remunerated certifying factory surgeon should be provided with a form on which he could set out in detail the full history and the exact distribution of the rash, and his grounds for opinion should be submitted and the blame-worthy substance named. The form should pass through the hands of the employer, who must describe in detail the occupation of the claimant and the procedure adopted at work. Mention should be made of probable chemical irritants. These documents might then be submitted to the medical referee, who, in consultation with a dermatologist, could give a decision. These latter two should have the power to compel in-patient observation for the testing of reagents on that particular skin, and simultaneous treatment could be given. Their report would enable a county court judge to arrive at an equitable opinion. Failing this, it would appear possible in county court cases for the "opposing" dermatologists to forward a joint report to the judge.

The writer, after considerable experience of this type of work, has yet to be concerned in a case where there was real divergence of dermatological opinion, however wide the breach may appear to become after skilled examination and cross-examination by experienced barristers.

DOROTHY TEMPLE CROSS RESEARCH FELLOWSHIPS IN TUBERCULOSIS

The Dorothy Temple Cross Research Fellowships in Tuberculosis for 1934-5 will shortly be awarded by the Medical Research Council, and applications should be lodged with the Council not later than June 1st.

The object of these Fellowships, as defined in the trust deed, is to give special opportunities for study and research to persons "intending to devote themselves to the advancement by teaching or research of curative or preventive treatment of tuberculosis in all or any of its forms." Candidates must be British subjects, and must possess suitable medical, veterinary, or scientific qualifications. They must also be able to produce satisfactory evidence of their ability to make good use of the opportunities offered by the Fellowships.

The Fellowships will preferably be awarded to candidates who wish to make their studies or inquiries outside the borders of Great Britain. They will be awarded for one year as a rule, but in special cases may be renewed. The value of the Fellowships awarded will depend in each case upon the standing and qualifications of the candidate, but will not be less than £350 per annum, payable monthly in advance. Travelling and some incidental expenses will be paid in addition.

It may also be possible to award a Senior Fellowship of considerably greater value to a specially well qualified candidate wishing to undertake an intensive study of some particular problem of tuberculosis at a chosen centre of work in another country.

Further particulars and forms of application are obtainable from the Secretary, Medical Research Council, 38, Old Queen Street, Westminster, S.W.1.

The council of Epsom College will shortly award a pension of £30 a year to a duly qualified medical man of not less than 55 years of age. If the candidate is a single man or a widower his income, independent of any allowance from the College or from the Royal Medical Benevolent Fund, must not exceed £100 per annum. Forms of application should be obtained forthwith from the Secretary, Epsom College, 49, Bedford Square, W.C.1, and must be returned completed to him not later than May 30th.

INSTITUTE OF MEDICAL PSYCHOLOGY

A YEAR'S WORK IN NEW QUARTERS

The annual meeting and luncheon of the Institute of Medical Psychology, London, was held at the Wharncliffe Rooms on May 7th.

At a preliminary business meeting Sir HENRY BRACKENBURY, the chairman of the council, said that 1933 had been a year of importance and change in the history of the Institute. It was the first complete year of work in the new building in Malet Place. It had been also marked, to everyone's great regret, by the resignation of Dr. Crichton-Miller from the position of honorary director, owing to the pressure of other work. The Institute itself and the work which centred in it were in large measure the outcome of his vision and of his practical mind. The foundation of the Tavistock Clinic in 1920 was an inevitable step in medicine and sociology, but that inevitableness did not detract at all from the gratitude which workers in this subject felt to Dr. Crichton-Miller. Fortunately he remained as honorary senior physician and a member of the council. In succession to the directorate they welcomed Dr. J. R. Rees, who also, by his vision and his practical mind, was more than any other man responsible for the achievement of the intermediate step in the Institute's history represented by the present admirable premises. Some of them were already looking forward to still larger and more suitable premises in which the Institute of Medical Psychology would take its proper place in the life of London and of the country.

Sir Henry Brackenbury added that the work of the Institute was both healing and preventive. In any problem of medicine healing was not to be achieved without at the same time accomplishing prevention. Every one of the cases treated at the Institute had potential tragedy behind it, which was often averted. He stressed also the educational achievements of the Institute, which he hoped would have its place in the British Post-Graduate School now in process of establishment under the auspices of the University of London and the London County Council. The main hospital in Hammersmith would certainly not be able to cater for all the different specialties in medicine which would be required for teaching purposes, and there might have to be certain outlying institutions associated with particular specialties, so that it was hoped that the Institute in due course might become a constituent part of the Post-Graduate Medical School. But the educational work of the Institute was not confined to the medical profession. It included classes and courses for social workers such as clergy and others, and the achievement of co-operation and co-ordination in this respect was not the least of the services which the Institute was rendering. It was mentioned at the meeting that the Institute had been able nearly to balance its budget, and that its volume of permanent support seemed to be increasing slightly. The relatively happy financial position, however, was due only to the fact that the majority of the workers were entirely honorary, while many of the others gave valuable service for quite inadequate remuneration. The number of new cases dealt with in 1933 was 893, and the hours of treatment reached the record figure of 14,500.

The Stage as a Psychotherapeutic Medium

The company then adjourned to luncheon, where the principal speaker was Dame SYBIL THORNDIKE, who gave a vivacious account of her experiences as an actress in relation to psychology. She said that it was natural to suppose that one's own particular job or special concern offered a panacea for various ills, but if the purpose of psychology was to enter understandingly into other people's lives, motives, and deepest feelings, then she thought the dramatic profession out of its experience had something useful to contribute to this subject. It was the actor's business to get "inside the skin" of somebody else and to see things through that other person's eyes. Nothing must be bidden or repressed or "kept dark"

when one was impersonating. Every quality, good or bad, must be known to the player. In ordinary life men and women succeeded fairly well in wearing a mask whatever their inward torments or ecstasies; such a mask would be fatal to the stage. She had found great advantage to herself in impersonating others. For two years she had experience of a theatre where plays were produced the theme of which was fear and terror, and although she had suffered previously from nightmare, she had no such visitation while acting in such drama. She got it "out of herself" by means of those shapes and forms of fear which she had to represent, and she learned that that was also the experience of some of those who witnessed the play; they were released from obsessions. The hidden thing being brought to light on the stage, those participating, on either side of the footlights, were able to "throw it off." Nothing was better for a difficult child than to get it to pretend to be somebody else. Dame Sybil also said that, once having played a character, it was impossible to dislike the character, however loathsome it might appear. For the understanding of other humans there was nothing like impersonating them.

Mr. GEOFFREY SHAKESPEARE, M.P., added a few words. As a junior Minister associated with the Ministry of Health he paid a tribute to the work done by the Institute. He was glad that the work was increasingly recognized, and he hoped that presently the larger local authorities would have clinics where skilled doctors were available to treat anxieties and worries in their commencing stages.

The closing address was given by Dr. J. R. REES, medical director of the Institute. He described the Institute as a place where people with complex frightening illnesses came, always by individual appointment, to work quietly with their doctors in environment which avoided the institutional atmosphere. The Institute was eclectic. Its workers included followers of Freud, to whom so much was owing; others saw in Jung the more helpful approach; while others, again, were influenced by Adler of Vienna (who was present at the luncheon and was given a cordial welcome). But actually most of them tended to be influenced by all three, and to use methods best adapted to individual needs. The annual "follow-up" results showed that from 31 to 36 per cent. of the patients reported themselves as permanently cured, but a further 30 to 41 per cent. reported material improvement, which had been maintained. The first day on which he made any serious contact with psychological medicine—in the room of the founder of the Institute—he saw a motto which had always struck him as particularly apt: *Guerir quelquefois, soulager souvent, consoler toujours*. Dr. Rees mentioned that, although not a clinic for delinquency, the Institute had had referred to it from the courts some 400 cases during the last five years, and had treated about two-thirds of them. Progress was also being made in fields of research. An anonymous donor had given £300 for an investigation in the after-results of sexual assaults on children, and this was but one of many possible fields in which research might be made.

It was announced that Prince George had consented to preside over a subscription dinner to be held on behalf of the Institute on June 26th.

According to M. Chendler (*Thèse de Paris*, 1934, No. 150), as the result of a recommendation made by the Académie de Médecine, the Director of Public Assistance in Paris in 1922 decided to create two centres for the collection and distribution of the serum of convalescents from measles, scarlet fever, mumps, whooping-cough, and poliomyelitis at the Hôpital Claude Bernard, the hospital for acute infectious diseases in adults, under the direction of Professor Teissier, and the Hôpital des Enfants Malades, under the direction of Dr. R. Debré. During the past ten years the results of serum prophylaxis of measles at the last-named hospital have been as follows: absolute prevention in 75 per cent., attenuation in 20 per cent., failure in 5 per cent.

THE CANCER HOSPITAL

OPENING OF NEW BUILDINGS BY THE QUEEN

The new wing of the Cancer Hospital (Free), in Fulham Road, London, was opened by Her Majesty the Queen on Wednesday, May 9th. The completion of this handsome building of six floors, named Granard House after the president of the hospital, the Earl of Granard, is an outstanding event in the history of this institution. It contains accommodation to the number of about thirty beds for patients of limited means, who can contribute towards the cost of their maintenance and treatment, and it also houses a new out-patient department and a new radiological department, the latter equipped with the most modern types of apparatus.

RADIOLOGICAL DEPARTMENT

The radiological department of the Cancer Hospital attained world-wide renown even as long as a quarter of a century ago, under the direction of the late Robert Knox, a portrait of whom, with an appropriate inscription, we are glad to see in a prominent place in the new building. The need for considerable expansion and development of this department has become more and more apparent. In order to further the closest possible co-operation between clinical work and scientific laboratory investigations well-equipped physical laboratories and diagnostic and therapeutic departments, fitted with the most modern types of apparatus, have been constructed, and occupy the upper three floors of the building.

These three floors are devoted respectively to physical investigations and the teaching of students, to x-ray diagnostic work and radium treatment, and to high-voltage x-ray therapy and artificial sunlight and electrical treatments. The whole department is under the direction of Professor J. M. Woodburn Morison, and the physics section is in charge of Mr. W. V. Mayneord, D.Sc. The Cancer Hospital is a school of the University of London, and in association both with the University and with the Royal Colleges post-graduate medical students are taught the clinical and scientific aspects of radiology, a lecture theatre and experimental laboratories being set aside for this purpose. Facilities are also afforded for the instruction of radiographers.

The radiodiagnostic section on the fourth floor is complete with the most modern provision, with special screening and radiography rooms, and large dark rooms, the walls and ceiling of which, by the way, are coloured deep crimson. The screening stands are beautiful pieces of engineering, the position of the patient and of the tube apparatus is adjustable at a touch. A feature of the radiography rooms is the timing switches. Radium therapy is also carried out on the same floor. The hospital possesses 14 grams of radium, and has had a further gram placed at its disposal by the National Radium Commission, so that it has been possible to develop radium beam treatment with considerable success.

The fifth floor is the chief pride of the radiological department, for it contains the high-voltage x-ray apparatus with which very high electrical pressures are obtained in order to obtain penetrating x-rays. The equip-

ment was constructed specially for the hospital by Ferranti, Ltd., of Hollinwood, near Manchester, and is the first of its kind in any hospital in this country. Its general appearance suggests a small power station. The design of much of the apparatus in this department and the conditions under which irradiation is carried out are the result of the work of the hospital's own experimental laboratories. One new device of some interest is the use of wireless apparatus to enable the patient in the cubicle to speak to the operator, who is some distance away in a separate room.

The total cost of the new wing of the hospital was approximately £150,000. The research of the radiological department is financed chiefly by the hospital itself, but valuable help is given by such bodies as the British Empire Cancer Campaign and the Medical Research Council, while the International Cancer Research Foundation of Philadelphia also assists in certain investigations.

THE OPENING CEREMONY

The opening ceremony took place in a large marquee in the grounds of the hospital. The Queen was received by the Earl of Granard, president of the hospital, who presented the Mayor of Chelsea, in which borough the hospital is situated.

At the entrance there were presented to Her Majesty Professor Filon (Vice-Chancellor of the University), Mr. P. J. Neate (chairman of the House Committee), Mr. Ronald Malcolm (treasurer), Mr. Jocelyn Swan (senior surgeon), Lieut.-Colonel Cobbold (secretary), and Miss Jacomb (matron). The Queen having been conducted to her place on the dais, Lord Granard made a speech of welcome, and Her Majesty then declared the buildings open. A number of further presentations then took place, including those of Mr. S. L. Loney (chairman of University Convocation), Sir E. Graham-

HIGH-VOLTAGE X-RAY TREATMENT PLANT

Little, M.P., Dr. E. Deller (principal officer of the University), Mr. L. Gwynne Jones (member of the General and House Committees of the hospital), Lord Horder (consulting physician), Mr. W. Ernest Miles (consulting surgeon), Dr. Stanley Wyard (physician), Mr. Cecil Rowntree, Mr. Percival Cole, and Mr. Cecil Joll (surgeons), Professor E. L. Kennaway (director of the Research Institute), Professor Woodburn Morison (director of the radiological department), and Mr. T. A. Pole (architect).

The Queen then left the dais and inspected various parts of the new building, and also of the older building, including the operating theatre floor and the pathological research departments. After Her Majesty had signed the visitors' book and departed, the whole hospital was thrown open for inspection. The Research Institute illustrated for the benefit of visitors the work carried on in recent years in connexion with the causation of cancer and the chemical and biological characters of malignant tumours. The investigations carried out on the origin of cancer have been concerned chiefly with chemical factors, and now show a record of definite achievement in the experimental production of cancer in animals. Attempts are now being made to determine whether the alteration in metabolism from that of healthy tissue to that of malignant tissue is brought about by the chemical agents which produce tumours in animals.

In addition to those presented, the guests at the ceremony, most of whom were wearing academic gowns,

included the Presidents of the Royal Colleges of Physicians and of Surgeons and of the British College of Obstetricians and Gynaecologists, the Master of the Society of Apothecaries, the President of the Royal Society of Medicine, the teachers of the University of London on the staff of the Cancer Hospital, the members of the medical and surgical staff and the staff of the Research Institute and Radiological Department, and of the General Committee and House Committee.

ACADEMIC REFUGEES

REVIEW OF A YEAR'S ASSISTANCE

A year ago the Academic Assistance Council was formed under the presidency of Lord Rutherford, with its seat at the rooms of the Royal Society, Burlington House, to assist university teachers and investigators who, on grounds of religion, political opinion, or race, were unable to carry on their work in their own country. The problem in its immediate form was created by the events in Germany, but assistance has not been confined to scholars and research workers of one nation, and several applications have been received from Russian, Austrian, Armenian, and Italian university teachers. Nor is the issue raised entirely a Jewish one, for many who have suffered or are threatened have no Jewish connexion.

A report of the council just issued states that it has received £13,223 in subscriptions, which, with £1,025 in the form of grants from Cambridge colleges, has enabled it to make maintenance grants at the rate of £250 a year for a married person and £182 for a single person, to forty-nine scholars to enable them to continue their research in universities in this country. Other agencies or local committees in England, co-operating with the council, have raised funds to provide maintenance grants for a further ninety displaced university teachers. Thirty-nine others are working in universities supporting themselves from their own resources, and industrial or commercial posts abroad have been found for several scientists who have been assisted by small loans for travelling expenses. A valuable information service has been built up and constant communication established with academic committees in the free countries of Europe and the American Emergency Committee in aid of displaced German scholars.

The funds of the council are now almost exhausted, but the Academic Assistance Council feels that it would be deplorable if the grants already made cannot be extended for a second year. If this is not possible the scholars and scientists will have no means of support, and the possibilities of help, or even of refuge in other European countries, have contracted since they were compelled to leave their fatherland. The council is very anxious not to betray into exile and destitution the wandering scholars for whom it has made itself responsible. The work of the council has a wider bearing than the meeting of a temporary emergency or a response to the promptings of compassion, strong as these considerations are. It states its purpose as the protection of academic freedom in which our culture has developed, and the preservation of universities as communities of free learning, not subject to temporary political dictations.

Some idea is to be gathered from the report as to the dimensions of the need. The number of those displaced from academic positions in universities or institutions of university rank is, so far as can be ascertained, 1,202, of whom 389 have been placed—178 in the British Isles and 211 abroad. In medicine the number displaced was 311, of whom forty-one have found positions in the British Isles and forty-two abroad, but it is agreed that the number placed is probably an understatement. Of the

178 placed in the British Isles, mostly in temporary research posts, Cambridge has taken thirty-one, Oxford seventeen, Manchester sixteen, Edinburgh six, and London sixty-seven. The medical schools and institutions in London have made accommodations as follows: Guy's, three; Lister Institute, two; London Hospital, one; London School of Hygiene and Tropical Medicine, one; Maudsley Hospital, three; Middlesex Hospital, four; National Institute for Medical Research, three; St. Mary's Hospital, two; University College Hospital, four; Westminster Hospital, two. Of those placed abroad fifty-eight have gone to the United States, forty-one to France, and twenty-six to Holland, while the reorganization of the University of Istanbul has created posts for thirty displaced German teachers. Extracts are given from reports on the work being conducted by German scholars in England; several researches in physiology are noted.

The council is appealing for £25,000 a year for the next two years to enable it to continue and consolidate the work already begun. "There is a great body of scholarship and technical experience which must be saved."

ST. BARTHOLOMEW'S NEW MEDICAL BLOCK

The second stage in the great rebuilding scheme of St. Bartholomew's Hospital is to be started at once with the erection of a block of buildings to house the whole of the medical wards. This will follow the new surgical block and operating theatres opened in 1930. The present buildings on the south side of the quadrangle, which date back to the middle of the eighteenth century, are to be demolished, and in place of their eight wards with twenty-five beds each, the new building on the site will consist of ten wards, each planned for twenty-three beds, thereby increasing the number of medical-beds by about thirty, and bringing the total bed accommodation to well over seven hundred. The new building will be constructed generally on the lines of the recently erected surgical block, with which it will be in communication on all its six floors. The Portland stone which faces the existing building will be retained to keep the architectural harmony of the square, but otherwise construction will be of brick. The cost of the building and equipment is estimated at £150,000. This sum is to be raised from capital by the realization of securities, and to be replaced by means of a sinking fund extending over sixty years. This will mean a loss of income on investments of about £5,000 a year, and it is anticipated that the expenditure of the hospital when the new block is available will be an additional £4,000 a year, so that St. Bartholomew's will be faced with the necessity of largely supplementing its present income. There is understood to be a great demand for a paying patient's block at Bart's, but under the existing charter the hospital funds cannot be used for any purpose other than the treatment of the sick poor. No doubt a supplemental charter could be obtained, but the hospital will find itself fully committed financially by its new building operations, and it looks as though a paying patients' block must await some specific benefaction.

We have received from Messrs. H. K. Lewis and Co., Ltd. (136, Gower Street, W.C.), the second supplement (1931-3) to the Catalogue of Lewis's Medical and Scientific Lending Library, including a classified index of subjects and authors. The main catalogue, revised to the end of 1927, with supplements 1928-30 and 1931-3, is supplied to subscribers at 8s. and to non-subscribers at 16s. The individual supplements may be had for 2s. each (to subscribers 1s.).

Ireland

Exclusion of Medical Officials from the Local Economies Bill

During the committee stage of the Local Services Economies (No. 2) Bill in the Senate, Sir Edward Coey Bigger moved the exclusion of medical officials from the operation of the Bill, which was supported by Senator Dr. W. O'Sullivan, and carried by a substantial majority. This amendment was accepted by the Minister for Local Government and Public Health in the report stage, and Sir Edward Coey Bigger said that the medical officers concerned would highly appreciate the action of the Minister, Mr. S. T. O'Kelly, and his sense of justice in excluding from the Bill an underpaid and hard-worked body of officials. Senator Surgeon Barniville and Senator Surgeon Oliver Gogarty by their attendance and support also contributed to the passage and acceptance of the amendment moved by Sir Edward Coey Bigger.

Treatment of Tuberculosis

Dr. Alice Barry, medical superintendent of the Peamount Sanatorium, reported that although increasing provision had been made in the various counties for advanced cases of pulmonary tuberculosis, yet the number sent for treatment at Peamount continued to be very high, and as the majority of these cases were chronic they clogged the beds and lengthened the waiting list, with the result that probable early hopeful cases were delayed admission and treatment. Surgical cases had been received during the year, and as many more refused. As there seemed no prospect of proper provision for these patients the possibility of a special department at Peamount might be considered. The delay in building a surgical unit had caused considerable inconvenience in carrying out the operations so essential in the treatment of tuberculosis. Every modern treatment was employed at Peamount as far as possible, but at present patients requiring major chest operations had to be sent to city hospitals, and that necessarily limited the work. The children's pavilion continued, said Dr. Barry, to hold a bright and happy place in their midst. During the year 142 children had passed through it, carrying away very happy recollections of their stay. Statistics showed that, of the 339 adult patients discharged, sixty-one came from Kerry, thirty-five from Kildare, Dublin sent thirty-one, Roscommon twenty-nine, Tipperary twenty-seven, Donegal nineteen, Wicklow eighteen, Galway thirteen. Among the male patients, the largest number, eighty-seven, had been engaged in agriculture, and of the women 100 had been employed in domestic or personal service. The maximum number of male cases treated fell between the ages of 20 and 25 years. Among females the ages were 15 and 20 and 25 and 30 years. In the course of an interesting talk on tuberculosis and its treatment Sir Pendrill C. Varrier-Jones of Papworth Village Settlement said that at Peamount they took these cases of men living in ordinary environments and treated them in both directions. The old regime was becoming out of date, and in many countries it had already gone. It would have to disappear. If they were going to put a man at rest, they should put him at rest. They were going to put him at rest by new surgical methods which were revolutionizing the treatment of tuberculosis. Putting a man at rest, if they did not make it possible for him to earn his living in the future, was doing only half their job. The longer they put a man at rest the greater the danger of making him morally incapable of returning to earn his own living. They had got to build up a training system, not only training his muscles back to earning capacity, but training his mind away from the

period of moral collapse to enable him to take up work once more. Once a man suffered from tuberculosis of the lungs he would suffer from it always. Therefore, they had to build up an environment in which such a man could work and earn his living without detriment to himself or his neighbours. This was their problem in a village settlement.

Women's National Health Association

The Dowager Marchioness of Aberdeen and Temair presided at the annual meeting of the Women's National Health Association. She expressed her thanks and the thanks of her family for the messages of sympathy on the death of Lord Aberdeen. The association, she said, had reason to believe that it had contributed something to the campaign against tuberculosis, which had resulted in a decrease in the death rate from the disease. It was now engaged in establishing an industrial settlement at Peamount, which opened up fresh hopes for ex-patients. Dr. W. S. C. Copeman, honorary physician to the Red Cross Clinic, delivered a lecture on "Rheumatism and Modern Medicine," and in the course of his address stated that if rheumatism were going to be tackled in the widest sense on a national scale, the whole thing had got to be part of a co-ordinated scheme. The present moment was an opportune one. He understood that in June of this year all approved societies were to be amalgamated into one whole. The position would then be comparable to that on the other side, and the societies would have surplus funds to devote to the question. He would deal with the disease under the head of chronic rheumatism. In County Dublin they were extremely fortunate in having an enlightened medical officer. Arthritis could be cured if taken in the early stages. Taken as a whole, rheumatism affected women three times as often as it affected men. Specialization was as necessary in this field, from the medical point of view and from the point of view of the laity interesting themselves, as in the field of tuberculosis. It was a whole-time job. The field of rheumatism to-day was in practically the same state as that of tuberculosis fifty years ago. If rheumatism killed people it would have had the attention of the public focused upon it many years ago. Tuberculosis was much less expensive to the country than rheumatism, which cost England and Wales £17,000,000 per year. Other countries had recognized the drain of this disease on their funds. Sweden had an extremely good scheme of treatment, as had Germany. Dr. T. G. Moorhead, President of the British Medical Association, said he agreed that it was necessary to tackle vigorously the group of rheumatic diseases. Although no statistics were available, he was certain that a thorough investigation would prove that, in proportion to the population, rheumatic diseases were as prevalent as in Great Britain, or probably more so. Ireland had been unfortunately notorious in the amount of chronic rheumatism existing among its inhabitants. He felt that there was just as much need for the systematic development of clinics in this country for children as for adults. Rheumatic fever was in all its manifestations a disease of childhood, and many of the disabilities in major life were due to the neglect of rheumatism in childhood. They could not avoid cold and damp in this country, but the care of school children should be improved. Some means should be provided in the schools for the drying of wet clothes and the changing of boots and stockings. Provision should be made for playgrounds, to prevent the children from playing on the damp streets. He was an advocate of throwing open the public parks of the city to the poor children. Dr. J. J. Harbison, county medical officer of health, said that just as tuberculosis was a matter of housing, so was rheumatism; and dietetics was another very important factor. It might be said of chronic

rheumatism: "It is more of a life to be lived than a disease to be treated." It was the duty of the State to encourage voluntary and other organizations to take up problems of this kind. Voluntary helpers might take the problem to the stage where the State would take it over.

Scotland

Aberdeen Medical Faculty

At a meeting of the Senatus of Aberdeen University on May 1st, with Principal Sir George Adam Smith presiding, it was agreed, in view of the large number of students who have been seeking entrance to the Faculty of Medicine, to limit the number accepted for the first year of medicine on October 1st, 1934, to 100. It was further decided that all applications for admission to medical study should be lodged before June 15th.

Tuberculin Test for School Children

A discussion took place at a meeting of the Fife County Public Health Committee, held at Cupar on May 3rd, regarding a periodic tuberculin test for school children. The test had been proposed by Dr. Munro, medical superintendent of Glen Lomond Sanatorium. Dr. G. Pratt Yule, medical officer of health for Fife County, said that if tuberculin tests were introduced it would be possible to know which children were infected and might later develop tuberculosis. The test aimed at the prevention of disease. The principle of the test was applicable to diphtheria, scarlet fever, and other diseases. A steady campaign for the immunization of children against diphtheria and scarlet fever would probably produce notable results, and was possibly more worthy of practical consideration than a similar procedure in regard to tuberculosis. It was true that the general improvement in sanitation and the keener hygienic outlook of the average citizen which had done much to combat tuberculosis in the past seventy years had done little for the common infectious diseases of childhood. The work proposed in regard to a tuberculin test could not be carried out, however, by the present staff of area medical officers. Several members of the committee spoke in favour of the procedure, and the report was adopted, but it was agreed to delay consideration of the introduction of the tuberculin test. At the same meeting it was resolved to instruct the medical officer of health to prepare a scheme for the provision of midwifery services for necessitous cases in Fife County.

Mental Hygiene

In an address on May 1st to the Soroptimist Club of Edinburgh, Professor D. K. Henderson, professor of psychiatry at Edinburgh University, said that the subject of mental hygiene needed much more publicity than it at present received, and that it was of equal importance with the treatment and prevention of physical disease. Positive work in the field of mental hygiene in Scotland had resulted largely from the activity of three individuals—two women and one man. The first was Miss Dorothea Lynde Dix, who came from the United States on a visit to Edinburgh in 1855. She was so much disturbed by what she saw in the smaller mental homes that she reported to the Home Secretary, with the result that a Royal Commission was set up to investigate the conditions under which persons suffering from mental diseases were treated; the result was the passing of the Lunacy Act (Scotland) in 1857. The second was Clifford Beers, another American, who had himself been a mental patient, and gave his experiences to the world in a book entitled *A Mind that Found Itself*. This led to the

setting up in Connecticut in 1908 of the first Mental Hygiene Society. The movement then instituted had grown to such proportions that representatives of fifty-three mental hygiene societies from many parts of the world had recently held a conference. The third was Miss Mary Russell, whose work resulted in the formation of the Scottish Association for Mental Welfare. Through the efforts of these and other pioneers the treatment of mental disorder was no longer regarded as taking place, of necessity, behind the walls of an institution; early treatment while the patient was still in his own home was now emphasized. Psychiatry was of great importance in industrial work, where nerve strain might be due more to mental than to physical causes. Mental experts were also necessary in law courts to examine persons guilty of repeated offences. The aims of those interested in mental hygiene should be the education of the public, the promotion of preventive measures, and the development of research.

England and Wales

Sir Willim Hodgson

While still in active practice, and holding office as chairman of the County Palatine of Chester Local Medical and Panel Committee and of the county council, Sir William Hodgson celebrates his eightieth birthday on May 13th. In honour of the occasion a presentation volume entitled *Fasciculus Cestriensis in Honour of Sir William Hodgson* has been prepared by his fellow practitioners in the county. The volume extends to 300 pages, and contains, in addition to a brief biographical note of Sir William, a collection of clinical memoranda written by some fifty-five Cheshire doctors, and a statement of the clinical facilities offered by the county's local health authorities. The copy to be presented to Sir William is printed on large paper and specially bound. Each member of the Cheshire Panel will receive a copy, and a certain number will be available for sale. Sir William has ever been a protagonist of the general practitioner, and it is hoped that this volume will be a fitting dedication to one of the most distinguished general practitioners of the day.

Compensation of Medical Officers by L.C.C.

Some compensation claims under the Local Government Act, 1929, have lately been considered by the Hospitals and Medical Services Committee of the London County Council. An ophthalmic surgeon who entered the service of the guardians as a part-time officer in 1923 and served until his appointment was determined in 1933 owing to the reorganization of the consultant and specialist service, and whose average annual salary during the last five years was £86, is recommended for compensation at rather more than £15 a year. The apportionment to which such an officer is entitled, including the appropriate addition under the Treasury scale, would be fourteen-sixtieths of his salary—that is, £20, but this is subject to the deduction of 25 per cent. usually made in the case of a part-time appointment. A pathologist who was appointed to a hospital in 1926, and whose appointment was terminated in 1933, received during the last five years of his service, with emoluments, £525, and the apportionment of ten-sixtieths of this amount, with the deduction of 25 per cent. as his office was a part-time one, brings the compensation to which he is entitled to £65 a year. This officer included in the emoluments for which he claimed compensation "use of laboratory, assistance of technicians, media, and materials," which is assessed at £200 a year. The committee, however, has found no evidence that he was entitled to make use of the staff and materials at

the hospital for private work, but in any case any benefit which he might have secured in that way could hardly be regarded as part of the remuneration of his position as pathologist to the hospital. He also claimed in respect of an increase of his emoluments which, he stated, would have been granted by the guardians had they remained in office; but the council has previously declined to take prospective increases into account in assessing compensation. The compensation recommended in his case is therefore the minimum annual sum of £65. A visiting pathologist whose service ranking for compensation is eight years is to receive eleven-sixths of his salary, subject to a deduction of 25 per cent. A tuberculosis consultant who entered the service of the guardians in 1924 and served until his appointment was terminated in 1933 received during his last five years a salary of £50, which would entitle him to compensation at the rate of £10 a year. Immediately after the determination of his appointment, however, he accepted a temporary position as medical officer of an open-air school at a salary of £66 a year, and is still serving in that capacity. The committee considers that the council is entitled to take the fact of this appointment into account, and as the salary now received is greater than that paid to him previously, the payment of the proposed allowance is to be suspended so long as he continues to receive a salary greater than £50 a year from the Council.

Overcrowding in "Shared" Houses

Speaking at a recent dinner of the Metropolitan Boroughs Standing Joint Committee, Sir Hilton Young, Minister of Health, said that he was closely occupied in working out, in consultation with local authorities, the Government's proposals for dealing with overcrowding. In London one of the worst aspects of the problem was the overcrowding in middle-class houses, which had been converted into working-class accommodation, and were used for lodgings or shared between several families. Only additional accommodation would cure this evil, and action for that purpose would be undertaken. Borough councils, however, should see that the conversion of middle-class houses into working-class accommodation was accompanied by proper precautions. Under existing by-laws, houses let in lodgings or occupied by members of more than one family required to be registered, and on the basis of the census there should be something like 130,000 such houses under the London County Council. Actually, the borough registers showed only about 21,000; it would not appear, therefore, that the borough councils were doing all they could to control these bad housing conditions in so far as they were covered by the by-laws. A permanent remedy for the evil of overcrowding depended in the long run upon the active and energetic enforcement of by-laws. As regards slum clearance, the Minister said that the biggest responsibility in London rested with the County Council, with whom it was essential there should be active co-operation on the part of the borough councils. There were some boroughs in which they would all be glad to see a greater spirit of energy, both in ascertaining slums and in taking the necessary steps for their clearance.

A Medical Buying Centre

British Industries House, a very large building in Oxford Street, close to the Marble Arch, which is being established as a centre for the use of wholesale buyers of Empire goods of all kinds—a sort of permanent British Industries Fair—is to have a medical section aiming to display all the equipment and material required by hospitals, public health institutions, doctors, and pharmacists. One large floor, comprising 8,000 square feet, has

been set aside for this purpose, and here it is expected to accommodate the showcases and display chambers of 150 British firms, with facilities for business discussions. Instead of having to travel round from one showroom to another, the prospective buyer will have a central depot where he can see all that the various manufacturers have to show him. It is estimated that hospitals and similar institutions alone in this country spend some sixty millions a year on equipment, and it is felt that a central clearing house would lead to more convenient and economical purchase and would stimulate British industry, for the house is reserved exclusively for goods from the home country or from the Dominions and Colonies. In the medical section, although this is not to be actually opened until the middle of July, half the space has already been allocated. An advisory council has been formed, of which Dr. Alfred Cox is chairman, and the other members are Sir Crisp English, Dr. E. P. Poulton, and Mr. A. R. Melhuish, past president of the Pharmaceutical Society, and the venture has the benediction of the British Hospitals Association, whose council is of opinion that a centre where samples of goods and equipment used in hospitals can be seen under one roof will be a great convenience to those interested in the management of voluntary hospitals and a useful stimulus to home industries. There are five other floors in which various industries, including textiles, leather, rubber, printing, metal, and furniture, are to show their samples and patterns. It is not to be an exhibition, and the general public will not be admitted.

History of the Sunderland Royal Infirmary

Dr. William Robinson, consulting surgeon, late chairman of the medical board, and a vice-president of the hospital, has told *The Story of the Royal Infirmary, Sunderland*,¹ in its social and historical setting, and has incorporated an outline of the growth and evolution of hospitals since their first appearance. Into this detailed but arresting narrative there enters the formation (by a committee of medical practitioners) of the Sunderland Humane Society in 1791, followed three years later by the emergence from it of the Sunderland Dispensary. This grew in size, and the title of Infirmary was added in 1810. Still further extension ensued, and in 1879 the Provident Dispensary had to be established as a separate institution to stop the abuse of charity by those who could afford to pay towards the cost of treatment. In 1864 land for a new hospital was bought, and three years later this was opened. Additions followed in due course, and in 1911 the prefix "Royal" was added by command of the King. Dr. Robinson has woven these and the many other events in the institution's history into a most informative and attractive discourse on the changing manners and customs and the emergence of scientific medicine throughout the world. A considerable part of the book is devoted to short notes from the hospital records, which throw a vivid light on the social evolution of the nation during the last 140 years. In addition to these there are chapters on pre-Reformation hospitals, the social condition of Sunderland from 1790 to 1832, the Tottenham Deaconesses, the Poor Law institutions, and other related subjects, in which the author combines a remarkable gift for vivid description with the interpolation of many comments, both critical and humorous, if at times a little partisan—a fact that adds some Attic salt to an already appetizing meal. The book will have a popularity far outside Sunderland, for it reveals the underlying reasons for many of the existing hospital traditions and principles which seem meaningless to those unacquainted with the history of the art of healing in this country.

Reports of Societies

THE CAUSATIVE FACTOR IN OTOSCLEROSIS

At the meeting of the Section of Otolology of the Royal Society of Medicine on May 4th, the Dalby Lecture was delivered by Dr. ALBERT A. GRAY, who took as his subject "The Otosclerosis Problem."

Dr. Gray began by describing two cases of women who had suffered from deafness for many years, and in whom it had been possible after death to make a pathological examination of the ear structures.

In one case typical porous bone of otosclerosis was found in front of and behind the oval window, and on one side a very thin bridge of bone caused ankylosis at the posterior extremity of the stapedio-vestibular joint. Both crura of the stapes were almost completely absorbed by newly formed fibrous tissue in the muco-periosteum, and degenerative changes were found in the medullary sheath of the cochlear nerve on both sides, and to a lesser extent in the neurilemma. Membranes were both normal, and no fluid or adhesions were present in either ear.

The other case presented a similar picture, with some thickening of the muco-periosteum over the external surface of the footplate of the stapes, the otosclerotic bone lying below undergoing absorption. An area of otosclerotic bone extended from 2 to 3 mm. in front of the oval window backwards along the footplate of the stapes to about 1 mm. behind the oval window, thus fixing the stapes in front and behind. Here again the tympanic membranes were both normal, as were the organ of Corti and ganglion spirale and other structures within the cochlea.

Using these cases as an illustration, Dr. Gray proceeded to defend his thesis that the essential causative factor in otosclerosis is, a slowly progressing failure in the function of the vasomotor reflex of the organ of hearing as a whole. In attempting to solve, even partially, the otosclerosis problem, the disease must be regarded in all its aspects—clinical, pathological, and general. The clinical facts included diminished secretion of wax, sluggishness or loss of the tympanic vasomotor reflex, deafness, tinnitus, raising of lower tone limit, and other symptoms. The pathological changes were to be found in the bone in the neighbourhood of the oval window along with the thickening of the muco-periosteum which sometimes accompanied it in the same region, and the changes in the medullary sheath and neurilemma of the cochlear nerve; the important fact that the nerves to the vestibule and canals remained healthy must also be considered. The general facts related to the conditions as to age, sex, and heredity, as well as the strange but very definite association of changes in the temporal bone with fragilitas ossium, osteitis deformans, and acusticus tumour. He pointed out that the change of bone in otosclerosis did not go on indefinitely, and it was also necessary to bear in mind that clinically the severity of the symptoms bore very little relationship to the change in the bone. The deafness might be extreme, and yet the ankylosis at the stapedio-vestibular joint might be quite small. In fragilitas ossium there were similar changes in bone and similar symptoms, but the changes were distributed in a different way. Otosclerosis was a disease of the organ of hearing, while fragilitas ossium was a disease of the bone generally. The same explanation held for the relationship of osteitis deformans to otosclerosis; in osteitis deformans the temporal bone was involved in the general condition. The relationship to acusticus tumour was in a different category. Here the lesion was actually in the acoustic nerve, and the vasomotor reflex interfered with was that of which sound was the stimulus. Consequently the change in the bone was found in those parts closely associated with the function of hearing; in texture, position, and other characters the bony change in acusticus tumour was identical with that found in otosclerosis.

The view he held with regard to otosclerosis was that the vasomotor system which governed the supply to the organ of hearing as a whole, right from the external meatus to the cerebral cortex, began to fail before its time; consequently all the tissues concerned in the function of hearing lost their blood supply to a certain

extent. It was not that the structures of the organ died, but that they were not sufficiently nourished to function adequately. The first of the pathological phenomena to be explained on this hypothesis was fibrous tissue in the region of the oval window. This was a degenerative process, with no inflammatory activity, and was due to the deprivation of the extra blood supply to the bone when it was subjected to stress by the movements of the stapes in response to sound vibrations. Every time the stapes moved, lines of stress occurred along the end of the ligament and spread out on to the walls of the oval window. As these passed round the cochlea they were rapidly dispersed into the large mass of bone which covered it, so that the chief stress on the walls of the window was nearest to where the movements of the stapes occurred. As long as the blood supply was good there was an extra flow of blood on the occurrence of the reflex, but if this were not forthcoming the blood stagnated in the veins, and the osteoblasts being deprived of proper nourishment, bone absorption occurred. The symmetry of the bone change was explained by the symmetrical distribution of the vasomotor nerves. The degenerative changes in the medullary sheath and neurilemma were similarly explained by the failure of the vasomotor reflex which normally afforded the extra supply of blood when the nerve functioned. On the other hand, the vestibular nerve remained healthy because it did not depend for its blood supply upon the vasomotor reflex arc of which sound was the stimulus.

Clinically, the loss or sluggishness of the tympanic vasomotor reflex, the loss of low notes, the negative Rinne's test, and continuous tinnitus, all suggested that some defect in the vasomotor system of the organ of hearing was the fundamental factor in the causation of otosclerosis. Continuous tinnitus could never result from the change in bone, and in cases in which the tinnitus was worst the change in bone was not extensive. The striking temporary improvement in hearing resulting from the inhalation of amyl nitrite and the occurrence of otosclerosis paradoxa showed that in many cases the deafness of otosclerosis was in large part the result of a functional, not a structural, defect in the organ of hearing. The rapidity with which this improvement occurred and then disappeared indicated that it was brought about by a sudden increase in the supply of fresh blood to the nerve structures of the organ of hearing.

Dr. Gray read a letter from a former patient who was a strict teetotaler. She had suffered from deafness for many years. On one social occasion she inadvertently partook of some alcoholic beverage. She experienced a distended feeling in the head for about half an hour, and for the rest of the evening she was able to hear every sound in the room. The restoration, however, did not persist until the next day.

The occurrence was only to be explained by an increased supply of oxygenated blood to nerve cells which had not been properly supplied for years. Turning, finally, to general considerations, Dr. Gray deprecated attempts to explain otosclerosis on the theory of some derangement of endocrine function or changes in bone metabolism. Otosclerotics were usually normal persons, differing only from other individuals by reason of their deafness. The increased frequency of the condition in women was not due to the direct effect of ovarian or other hormones upon the organ of hearing, but to the fact that at every menstrual epoch, and still more during pregnancy, the whole vasomotor system was disturbed, and if there was an innate weakness in any one part of that system, such as the organ of hearing, that part would be prone to damage. Women were therefore, on the whole, more liable to otosclerosis than men, and the relative failure of the functioning of the vasomotor reflex was more transmissible by women. On the basis of an experience of thirty years, and the assembly of the pathological and clinical facts, he urged that a case had been made out for explaining otosclerosis by a failure of the vasomotor reflex function of the organ of hearing.

Dr. W. J. HARRISON thanked Dr. Gray for his very clear presentation, and said that otologists would have no further excuse for using "otosclerosis" loosely to denominate all cases of a doubtful or irresponsive nature.

CORRESPONDENCE

Quinine versus Atebrin and Plasmoquine

SIR,—I was interested to read the articles on the treatment of malaria by atebrin in your issue of March 17th, by Drs. P. D. Johnson of Perak (p. 473) and E. J. R. MacMahon of Trinidad (p. 477). The treatment of malaria by atebrin and plasmoquine constitutes a distinct advance in malarial therapy, but Dr. Johnson's conclusion that atebrin is definitely superior to quinine in all types of malaria, and that it destroys the malarial parasites more rapidly than quinine, is perhaps too optimistic as a general statement, although no doubt true in his own experience of the disease acquired under natural conditions.

There is at least one type of malaria in which quinine is sometimes more certain in its action than either atebrin or plasmoquine, and that is the malaria induced in the treatment of neurosyphilis. The observation that quinine is more certain and rapid than plasmoquine or atebrin in stopping the course of the paroxysms of a malaria induced for therapeutic purposes cannot be peculiar to this hospital, but at the moment of writing I am not in a position to quote other observers in support. My colleague, Dr. H. S. Hensman, superintendent of the Government Mental Hospital, Madras, informs me that he always uses quinine in cutting short the malarial attack in the treatment of his induced cases, and finds it most satisfactory; he has not had any reason to try atebrin. I personally favour the intravenous injection of 5 grains of the hydrobromide of quinine for terminating the fever in induced malaria.—I am, etc.,

ROBERT E. WRIGHT, C.I.E.,
Lieutenant-Colonel I.M.S.

Superintendent, Government Ophthalmic Hospital,
and Professor of Ophthalmology, Medical
College, Madras.

Madras, April 12th.

Jejunostomy in Hyperemesis Gravidarum

SIR,—In a discussion on hyperemesis gravidarum at the Royal Academy of Medicine in Ireland, reported in the *British Medical Journal* of April 21st (p. 723), my name is mentioned by Dr. Bethel Solomons as suggesting the operation of jejunostomy for the relief of this condition. A word of explanation is needed, as the subject is outside the territory of the general surgeon.

Three years ago a case was admitted under my care to the surgical wards of Mercer's Hospital before a diagnosis had been made by the attendant practitioner. Some days elapsed before a transfer could be arranged. During this period there was incessant vomiting and symptoms of toxæmia combined with nervous phenomena, which were akin to those seen in the acute phases of hyperthyroidism. The patient was critically ill. All commonplace remedies were ineffectual in relieving the symptoms. Repeated aspirations of the mucous contents of the stomach through a Jutte tube were without avail. The rectum refused to retain any adequate quantity of fluid; interrupted attempts at intravenous medication were such an ordeal to the patient that they were discontinued. On general principles the operation of jejunostomy was recommended, but it was declined.

Subsequently I raised the question at a meeting of the Section of Pathology of the Academy.¹ The general opinion after the meeting appeared to be that there was a place for the operation in selected cases. It was, however, insufficiently realized by those not engaged in intestinal surgery that the operation of jejunostomy could be performed in a few minutes under local anaesthesia,

and that the catheter introduced could be kept in position without leakage for an indefinite period of time. Solutions of glucose, all forms of fluid nourishment, and aperients, when necessary, could be administered without hindrance. The stomach was put out of action and gastric reflexes disappeared. Carbohydrates given in plentiful supply restored liver function, acidosis was prevented, and cardiac function improved.

From the therapeutic standpoint some cases of hyperemesis gravidarum appear analogous to those with renal and hepatic insufficiency from other causes, and to the well-known toxæmias which so often respond dramatically to a liberal supply of carbohydrates and fluids. Had time permitted in the case in question "venoclysis"—that is, the continuous administration of glucose by the drip method into the veins—might have been effective. I have referred to the excellent results obtained by this means in cases of hyperemesis gravidarum in the *Medical Annual* of 1931 (p. 377), and also to its efficacy in intestinal conditions (*British Medical Journal*, 1932, ii, 540). Since then the method has received more attention, and should be tried, I think, before recommending jejunostomy in the cases under review. Dr. O'Donel Browne, late assistant master to the Rotunda Hospital, has now reported a case of jejunostomy for the relief of severe hyperemesis gravidarum; the operation was successfully performed by my colleague Mr. Owens.

I hope that obstetricians will consider the operation worthy of an extended trial, so that evidence may be obtained from the results of a series of cases. Specialists alone can select the suitable cases and decide the time in each instance when the more orthodox methods of treatment should be reinforced.—I am, etc.,

London, W.1, May 7th.

W. I. DE C. WHEELER.

Treatment of Anaphylaxis by Adrenaline

SIR,—Dr. H. R. R. Mavor is to be congratulated on the success of his treatment of the case of severe anaphylaxis described by him in your issue of May 5th. His conclusion that "the dramatic effects of the administration of adrenaline on the milder symptoms suggest that much larger quantities of the substance could have been given in the first instance and repeated more frequently" prompts me to describe again the method of treatment by continuous injection of adrenaline, which I have used for status asthmaticus for several years and which I have also found very effective in a number of cases of anaphylaxis, two of which were as severe as those described by Dr. Mavor.

A syringe is filled with adrenaline chloride (1 in 1,000) and the needle introduced hypodermically. An initial injection of two or three minims is given, and then one minim is injected every thirty, forty-five, or sixty seconds, according to the reaction of the patient. In asthma the initial dose should be the largest one which the patient knows from experience gives rise to no unpleasant symptoms, and the rate of the subsequent injections is such as to cause no change in the pulse and no other effect except relief of the asthma. In anaphylaxis the dosage is a matter of guesswork: it is best to begin with three minims and then to give one minim every half-minute for five minutes, after which one minim is injected every minute until complete recovery takes place. In one case of exceptional severity it was necessary to continue the treatment for an hour and a half. I believe that death from anaphylaxis would never occur if the continuous adrenaline treatment was always promptly instituted.—I am, etc.,

New Lodge Clinic, Windsor
Forest, May 7th.

ARTHUR F. HURST.

¹ *Med. Press and Circ.*, December 16th, 1931, p. 480.

Hereditry and Mental Deficiency

SIR,—My paper on this subject has received attention from Dr. J. S. Manson, Dr. C. P. Lapage, and Dr. F. Grundy in letters which appeared in the *Journal* of April 7th (p. 641) and April 21st (p. 727). Your correspondents write from extensive experience and study of the subject, and I appreciate their comments and criticism. Will you allow me to reply briefly?—

Criticism by correspondence, on so large and complicated a subject, can only be made and met in a broad way. My critics bring several objections against the claim that Dr. Thomson's cases are a fair sample of all types and grades of mental deficiency: they say that many slighter cases cannot be recognized under 5 years of age, and that his cases consisted largely of the more severe ones. I cannot take up your space by a full discussion of these objections. I assisted Dr. Thomson in his hospital clinic for ten years, and I can testify that there were large numbers of slight cases among the total. Also, since his death, my own case records in this clinic now number about 400; they also include a large number of less severe cases, and the great majority of these were submitted to me before 5 years of age. My opinion, based on clinical experience, is that one can obtain the best sample of all types and grades of mental deficiency in early childhood; and at this age one can obtain a fuller history, both of the individual and of the family, and can conduct a more searching clinical examination of the child. Dr. Thomson's limitation of age must have excluded cases of syphilitic dementia, encephalitis, and epilepsy, and no doubt of some slight cases of primary amentia. But the total number of these must have been small, and, in my view, unable to disturb seriously the proportions of ante-natal, natal, and post-natal types which his figures show.

Dr. Manson suggests, and correctly, that Dr. Thomson did not go deeply into heredity in the group, simple primary amentia (292 cases). That would have been a task beyond the powers of any man. And let it be granted that heredity plays a part in this group: but the extent of the part, and the manner of its working, remain at present unknown: and the group forms only a third of the aggregate of cases. What do we know of primary amentia? All we know about mongols is that we can recognize them by their external marks, and we have given them a name: and we know even less than that about simple primary amentia. This kind of knowledge is only "the ignorance of foolish men." The theory of a hereditary neuropathic constitution is a gallant attempt to fill a part of this great void that we call primary amentia. But it will be seen that the action of heredity in such a constitution is what the logicians call *permissive*; and that to produce mental deficiency some other releasing factor, non-hereditary in character, is required.

Let me state some main issues. Are Dr. Thomson's thousand cases a fair sample of all types and grades of mental deficiency as it occurs in all classes of the population? If they are, their analysis shows a clear majority of non-hereditary cases. This conclusion is flatly opposed to the teaching of many authorities on the subject. But such reversals of established opinion have happened before. Fifty years ago most of the authorities were agreed that tuberculous disease was hereditary: and we know now that they were wrong. It also puts a different complexion on the eugenics propaganda upon mental deficiency that goes on. In public lectures, in sermons, in letters to the Press, our people are led to believe that mental deficiency is one disease, and is hereditary, that it is a kind of race poison that has crept into our human stocks, that it is spreading underground like the musk rat, and that ruthless methods of extermination, more akin to veterinary surgery than to medicine,

are needed to stamp it out. The analysis of Dr. Thomson's cases seems to me to knock away the prop that supports all this scaremongering propaganda.

There still hangs over the mentally deficient that cloud of ignorance, fear, loathing, and not a little cruelty, which has now been lifted to a great extent from the insane. It will be gradually dispelled when we know more of the ante-natal causes of the condition. To attain that fuller knowledge further clinical study is required. But enough is known at present to justify the statement that heredity is a minor and not a major factor in the production of mental deficiency.—I am, etc.,

Edinburgh, May 2nd.

CHARLES MCNEIL.

The Cancer Problem

SIR,—I gather from the notice in your issue of May 5th of Mr. Lockhart-Mummery's book, *The Origin of Cancer*, that the author assumes civilized man not to have "been subject to the law of natural selection for some thousands of years." Is this a legitimate assumption? Some years ago I made the suggestion that all deaths occurring before the termination of reproductive life, not due to violent causes, are instances of natural selection: they constitute, in large measure, eliminations of the unfit—those who are unable to adapt themselves to their environment.

It is well known that under natural conditions elimination takes place to a stupendous extent. It is most rigorous in the case of those species which maintain much the same population from year to year. When a species increases year by year, the process of elimination becomes less, but on the whole only slightly less, until sooner or later the increase reaches a limit.

At the introduction of agriculture (which initiated the era of civilization) the total human population did not, perhaps, exceed 10 millions. Such a meagre population shows how rigorous the process of elimination must have been during the long period of man's evolution from the anthropoid to the agricultural phase (some seven thousand years ago). Since that date the human population has increased by 1,500 millions or more. This has, of course, involved a slackening in the process of elimination. Nevertheless, elimination has been proceeding briskly. Consider how greatly the human population would have increased since the introduction of agriculture if all humans had been permitted to survive the reproductive period and there had been no hindrance to procreation. Allowing four generations for each century, and four children to each couple, the population would double itself four times each century, and $4 \times 70 = 280$ times in seventy centuries. At this rate it would, in less than a thousand years, have exceeded a million million, a figure by the side of which our present population pales into insignificance indeed, being in the proportion of a million million to fifteen hundred million! After seven thousand years the increase would have reached a figure inconceivably greater.

We must conclude that, since the advent of agriculture and civilization, a vast number in successive populations have been prevented from leaving progeny, and thus have been racially eliminated; and, further, that the elimination has in large measure been an elimination of the least fit, of those least capable of coping with their environment: to that extent natural selection has been in operation.

I am not suggesting that the process of natural selection has not slackened—undoubtedly it has, notably in this country during the past half-century, and this, no doubt, is leading to racial deterioration. Cancer, occurring as it usually does in later life, comes, in only a minor degree, under the beneficent action of natural selection. Victims to cancer have generally been afforded abundant opportunity to leave offspring.—I am, etc.,

London, W.1, May 5th.

HARRY CAMPBELL.

SIR,—The review entitled "The Cancer Problem," in your issue of May 5th (p. 803), begins with the statement: "The fact that cancer is much more frequent among civilized than savage races, and is increasing in frequency, is one of the outstanding features of the disease." This statement contains two hoary fallacies which have been exposed over and over again, and which should not be allowed to be perpetuated in one of our leading medical journals without a protest. Any comparison of the incidence of cancer between any two populations presupposes as an essential condition, first, an efficient medical service which ensures a reasonably accurate diagnosis and certification of the cause of death, and, secondly, an efficient system of recording the births, deaths, and ages of the population as a whole. Since these two conditions do not exist in the savage races, nobody can possibly know whether cancer is more or less frequent in them than in civilized races. For native races in which these conditions are fulfilled it has been shown repeatedly that they are affected by cancer about as frequently as civilized races, although the organ incidence may be different.

The statement that cancer increases in frequency in civilized races is true only if one takes the crude figures; but these are misleading, since they neglect such essential factors as alterations in the age constitution of the population, improved methods of diagnosis, and improvements of the certification of the causes of death.

This subject is too big to be discussed within the scope of a letter to the Editor. It must be sufficient to state that when these factors are taken into consideration the increase shown by the crude figures becomes greatly diminished, and that according to a recent paper by Dr. S. Peller (*Zeit. f. Krebs.*, 1934, xl, 465) there is actually a diminution in the incidence of cancer in the age groups up to 60 years, and only the age groups over 60 years show an increase. Since the alleged "fact" quoted above is partly an error and partly doubtful it can hardly be described as an outstanding feature of the disease.—I am, etc.,

London, May 5th.

W. CRAMER.

SIR,—I am in agreement with much of what "M.D." has expressed (*Journal*, April 28th, p. 777) and consider that he is emphasizing an important point of view. Without wishing to be controversial, I find it difficult to agree that the recovery of enzymic activity in the blood serum of cases, after the removal of cancer, necessarily proves that the previous deficiency was the effect rather than an associated cause of malignancy.

During the past two and a half years I have had the opportunity of carrying out systematic serum tests upon a large number of cases and have increasing evidence that the earliest manifestation of cancer, as well as of recurrence or metastases in known cases, is preceded by abnormalities in the serum collateral with enzyme deficiency, frequently recognizable many months, and in some cases approximately a year, before the clinical condition was apparent. Further, in some cases an improvement in the serum findings had commenced before the cancer had been removed, and this apparently natural immunizing response appears to be of good prognosis. The further improvement in the serum findings which may follow the removal of the primary growth is probably associated with serum changes and improved resistance, which have been shown experimentally to follow particularly lysis of malignant cells *in situ*. In cases in which no such return towards normal of the serum reactions follows surgical or radiological treatment, the prognosis is relatively serious. These consecutive observations suggest that cases of cancer whose clinical condition and serum shows a reasonable response should be consistently followed up by post-

operative treatment with the object of maintaining and restoring a normal serum reaction, and with this the re-establishment of an effective cytolytic defence against recurrence. Of the blood tests employed for the purpose of such observations, the modified Bendien reaction I find is one which so far gives most satisfactory information.

It would be interesting to know if others can confirm "M.D.'s" experience of tuberculous cases being immune to cancer. My own rather limited observations have not found this so, and a late physician of considerable clinical experience used to state that the healed tuberculous patient was subject to cancer.—I am, etc.,

Liverpool, May 2nd.

E. CRONIN LOWE.

The Cancer Campaign

SIR,—Your readers will remember that in July last the Duke of York suggested that an appeal should be instituted on Empire Day (May 24th) in aid of the funds of the British Empire Cancer Campaign. In accordance with this so graciously expressed wish, the Appeal Committee of the Campaign has been able to organize this day in over 1,000 centres throughout the British Isles, and in different parts of the Empire other activities are taking place. In the metropolitan area and the City of London a flag day will also be held on Empire Day. I recently received a letter from His Royal Highness, of which the following is an extract:

"It is with great satisfaction that I have learned that the scheme suggested by me at the annual general meeting of the British Empire Cancer Campaign at the House of Lords in July is about to be carried into practical operation on Empire Day, May 24th. . . . I shall be grateful for any help that can be given to this Empire Day effort."

May I through your columns appeal for helpers for these "Empire Day" flag days? We have already been successful in recruiting a large number of depot helpers and sellers, but, if the day is to be the success so necessary to obtain adequate funds to fight the cancer scourge, it is essential that we should recruit very many more sellers and helpers. I earnestly appeal to all who are interested in this great cause to rally to this call for help, and to send their names to me at 12, Grosvenor Crescent, Hyde Park Corner, S.W.1, stating where they would be willing to help, and I will see that they are put in touch with the appropriate depot organizer.—I am, etc.,

READING,

London, S.W., May 6th.

Chairman, British Empire Cancer Campaign.

Vaccine for Acute Gonorrhoea

SIR,—I have read the paper by Dr. Orpwood Price and Dr. Ambrose King (*April 28th*, p. 748) with interest, and also with some satisfaction at the thought that a useful method of treatment is being more widely employed. But the vaccine which the authors describe as new does not appear to differ in its preparation from the earlier type of detoxicated vaccine described by Thomson, and which was incorporated in my method of preparing residual vaccines (*British Medical Journal*, 1921). The apparent passage into solution of the organisms is due to swelling and change of refractive index in the presence of weak alkali. Some of the cocci disintegrate, but a large proportion are still recognizable in stained preparations. During the process of acid precipitation certain toxic factors remain in solution while the body proteins and exotoxin flocculate: the method is widely used to-day for the concentration of exotoxins. In residual vaccines the exotoxins are probably present in the form of toxoids, produced by the action of hydrogen peroxide and heat used in the preparation.

In the original paper on residual vaccines the results of treatment with the simple acid-alkali vaccine were compared with those obtained by the full technique for the preparation of residual vaccines, and it was clear that the latter gave superior results. The violent local reaction described as "good" by Dr. Price and Dr. King is due to incomplete removal or destruction of the toxic agent remaining in solution.

McCrea (*British Medical Journal*, May 5th, 1928) published the results of treating 134 consecutive acute cases with residual gonococcal vaccine and compared them with 140 controls. He found indisputable evidence of the efficiency of the vaccine, and his views on that point were supported by Burke, who had obtained similar results at Warrington.

The standard of cure adopted by Dr. Price and Dr. King includes two instrumental investigations which many urologists would regard as barbarous, if not definitely harmful, when not dealing with chronic infections. Furthermore, the two-glass test as used by us rarely allows disease of the genital or lower urinary tract to escape detection. The criterion of cure by the two-glass test adopted by McCrea seems to be more stringent than that used by Dr. Price and Dr. King. In the former case not more than three cells per field, using 1/6 objective, from the centrifugized deposit from the second glass after prostatic massage, is required. Examination of the prostatic bead with an oil-immersion objective has rarely been used by me as a criterion of cure, but I certainly would not pass five cells to a field as satisfactory.—I am, etc.,

Manchester, May 1st.

C. E. JENKINS.

Poisoning by Ground Ivy

SIR,—Now that spring is upon us once again I would like to draw the attention of amateur gardeners to the danger of handling the common ground ivy plant. It is so common that it finds its way into nearly every garden, and consequently it is almost certain that it will be handled either by the doctor turned gardener or by some of his patients.

For long I did not recognize that the merest touch of the leaves or stem of this plant could give rise to a most violent irritation of the skin of the hands and arms. The first attacks were diagnosed as scabies, cheiropompholyx, etc., and appropriate remedies were prescribed, but without much, or indeed any, benefit. It was only after several separate attacks that I recognized that the actual cause was due to contact with the "rare old plant." The merest touch of the leaves or stalks gives rise after an interval of a few hours to the most intense itching. Soon afterwards redness with swelling of the skin on the back of the fingers develops. This goes on to papular and vesicular formation: the latter is so constantly present in the webs of the fingers as to simulate scabies, but only in a very few instances do pustules form. Small bullae often run in a circinate form, and are probably the result of irritation at the points of contact. The eruption is, however, so widespread over the skin of the hands that it cannot be caused by direct contact all over the surface, but must be due to a spreading of the toxin through the lymphatics. The affection persists for several days, and then gradually fades, with slight desquamation.

It is well known that the ordinary climbing ivy is an irritant to the skin, but usually it acts only as such when roughly handled, and when the leaves are broken so as to allow escape of the juice. I do not think, however, that the exceedingly irritant properties of the creeping variety are so well recognized.

The only treatment which relieves the irritation and allows of sleep is bathing the hands in very hot water, with the subsequent application of oxide of zinc ointment.—I am, etc.,

W. G. AITCHISON ROBERTSON,
Bournemouth, May 6th. M.D., F.R.C.P.E.

Bee Venom for Rheumatism

SIR,—I used bee venom for rheumatism in the summer of 1911, and looking through the notes of some thirty cases which I had at that time, the results obtained appear to have been so satisfactory that it is difficult to understand why I gave it up. I made my own solution, but I remember there was much of the Isle of Wight disease about that year, and bee keepers were very jealous of their stock. As the winter came on it became impossible to get them, added to which the remedy seemed to lose its value, even when I did manage to get enough bees for the purpose.

During this last winter a doctor's wife and a former patient of mine was so enthusiastic about the value of the bee sting venom that I had given her in 1911 that I promised to make her some more. This was last Christmas-time, and just then I had as one of my asthmatical patients a very experienced and scientifically knowledgeable bee keeper: she informed me that bees sting her many hundreds of times a year, and by their stings she would be able to tell which month of the year it is. The stings vary enormously, and are most potent at the end of summer, when the honey is being guarded before the winter starts: during the winter the potency sinks very rapidly; hence, no doubt, my failure with treatment during the winter months.

As I now have sufficient bee venom for my own use, and some to spare, I shall be pleased to supply Dr. Shipton and Dr. Barnes in order that they may try its efficacy. One of my most remarkable cases was a child with acute rheumatic fever, high temperature, swollen joints, the usual sweating, and other symptoms: after five daily injections the child was perfectly well. It would be interesting to know if it has been tried at Buxton in this acute type of case.—I am, etc.,

London, W.1. May 1st.

FRANK COKE.

The Milk Question

SIR,—In reply to Dr. Hawthorne's letter, I submit that anyone reading the report issued by the People's League of Health could only come to the conclusion which I stated.

In regard to the question as to whether "clean" milk infected with tubercle bacilli is less infective than dirty milk containing the same number of tubercle bacilli, the statement I made was that "an all-round clean milk means fewer cases of tuberculosis despite the presence of tubercle bacilli." Clean milk will, of course, contain fewer bacilli than dirty milk. Tuberculosis is recognized as a disease which more readily develops and becomes clinically evident in the presence of a lowered local or general resistance. It is agreed that dirty milk may give rise to septic throats and gastro-enteritis, for instance, and it is surely a reasonable assumption from the point of view of the ordinary medical man that in these cases the bacillus will find a more ready entrance, and subsequently a more suitable nidus for growth, than in cases where there are no other adverse factors. The tuberculous diseases I had in mind at the moment were tuberculous meningitis, glands in the neck, and tuberculous peritonitis. There is no definite evidence either way, but I contend that the weight of evidence is in my favour.—I am, etc.,

Hounslow, May 7th.

W. S. FORBES.

Cataract and Vitamin Deficiency

SIR,—Dr. F. P. Fischer's letter in your issue of April 28th (p. 776) would have been more valuable had he been able to state that in cataract patients he had, in the other tissues of the body, detected a vitamin B₂ deficiency corresponding to that found in the lens.—I am, etc.,

London, May 6th.

J. BARCROFT ANDERSON.

Practical Therapeutics

SIR,—I am very grateful for the kindly and appreciative opinions expressed by the reviewer of my *Handbook of Therapeutics* in your issue of April 28th. But the review contains two rather serious misstatements of fact.

1. I am alleged to state in my book that for free haematemesis "operation is the only treatment, and is best performed at the earliest possible moment." If your reviewer will look again at page 314, he will see that the quotation he gives refers to the treatment of *perforation*—quite a different matter.

2. I am alleged to have little faith in blood-letting—mainly, it would appear, on the ground that the word "venesection" does not appear in the index. Yet I describe the method of puncturing a vein—the usual method employed at the present time for blood-letting—and on pages 238, 271, 283, and 373, when discussing respectively the treatment of certain types of cardiac disease, oedema of the lung, uraemia, and polycythaemia, I express the opinion that the removal of blood from a vein is a useful, and in some cases an excellent, therapeutic measure.—I am, etc.,

University of Aberdeen, April 28th.

DAVID CAMPBELL.

** The reviewer writes: I owe Professor Campbell an apology. I overlooked, as I ought not to have done, the heading of a new paragraph which indicated that, the proposal of immediate operation referred not to haematemesis but to perforation of the stomach. On his second point, I must still maintain that to describe the method of intravenous medication does not compensate for the absence of directions for withdrawal of blood from a vein, and that the index of his book might have been improved on the points I suggested; his present reference, indeed, illustrates this claim.

A Fund for Exiled Jewish Doctors

SIR,—May I beg the hospitality of your columns for an appeal to Jewish practitioners to contribute to the fund which the Jewish Medical and Dental Emergency Association has instituted for the settlement of displaced Jewish medical scientists? It is common knowledge that a great amount of scientific work of the highest importance has been disturbed and threatened with extinction by the present policy of racial exclusion in Germany; and it is its recognition of its special duty to preserve for humanity what it can of this valuable work which has caused the association to devote its fund to this purpose.

It is proposed to use the bulk of the money collected to settling Jewish medical scientists in Palestinian institutions (the Hebrew University, the Hadassah Hospitals, etc.), where the association has already been instrumental in establishing several such workers, and it is hoped, by the collection of a substantial sum, to enlarge these possibilities. I would therefore desire to draw the attention to the fund of such practitioners who have not been apprised of the work of the Association, and to solicit their co-operation. Donations should be sent to

the treasurer, Jewish Medical and Dental Emergency Association, Woburn House, Upper Woburn Place, W.C.1.—I am, etc.,

L. PHILLIPS, M.B., B.Ch.

London, W.C.1, April 26th.

Honorary Secretary.

Humane Destruction of Animals

SIR,—In reference to your annotation on this subject (*Journal*, April 28th, p. 764) I think it will be of interest to your readers to know that every aspect of small-animal destruction is undergoing detailed scientific investigation by veterinary experts at the instance of the National Veterinary Medical Association. In the course of this work, which was initiated about a year ago, every phase of the subject will have been thoroughly investigated, and it is confidently anticipated that, as a result, this association will eventually be in a position to make an authoritative pronouncement on the relative merits of all forms of euthanasia.—I am, etc.,

F. KNIGHT,

General Secretary, National Veterinary Medical Association of Great Britain and Ireland.

London, W.C.1, April 28th.

The Services

DEATHS IN THE SERVICES

Colonel Thomas Stodart, C.I.E., Madras Medical Service (ret.), died at North Berwick on April 15th, aged 66. He was born on March 13th, 1868, the son of William Stodart of Winton Hill, Penciland, East Lothian, and was educated at the Royal High School, Edinburgh, and at Edinburgh University, where he graduated M.B. and C.M. in 1891. In 1893 he joined the Indian Medical Service, and after serving in the Sudan in 1896, for which he received the Egyptian and the Khedive's medals, and on the North-West Frontier of India in the Tirah campaign of 1897-8, he entered the Burma Civil Medical Department in 1898. He was recalled to military duty in 1914, and posted as A.D.M.S. of the Banna brigade; for his part in the Afghan War of 1919 and the Waziristan campaign of 1920 he was mentioned in dispatches. Retiring shortly afterwards, he returned to North Berwick, where he took a great interest in public affairs. He was a member of the East Lothian County Council, of the Joint Sanatorium Board for the South-Western Counties, and of the Public Assistance Committee. At the time of his death he had been president of the North Berwick branch of the British Legion for five years. He was a keen golfer and also engaged actively in curling and shooting. He is survived by a widow, two sons, and two married daughters.

Colonel Christopher William Carr-Calthrop, C.B.E., Bengal Medical Service (ret.), died at Ealing on April 17th, aged 89. Born on July 28th, 1844, the eldest son of William Charles Calthrop of Withern, Lincolnshire, he was educated at Merchant Taylors' School, Charing Cross Hospital, and Heidelberg University, where he graduated M.D. in 1869, after taking the M.R.C.S. in 1867 and the L.R.C.P. Lond. and L.S.A. in 1868. He entered the Indian Medical Service as assistant surgeon on April 1st, 1869, passing first into Netley, where he won the Herbert prize as first man of his term. He attained the rank of full colonel in April, 1899, and retired in April, 1904. In the Afghan War of 1879-80 he took part in the action at Ali Khel, and in the operations in and around Kabul, was wounded, and gained the Afghan medal with a clasp; and for his services in the Sudan, as principal medical officer in the Dongola campaign of 1897, he received the Egyptian medal and the Khedive's bronze star. When the Great War began he was appointed recruiting officer for Ealing and district, and later, in 1917, was engaged in making ivory insulators for the Admiralty, ivory turning having been one of his hobbies. For some years, during his service in India, he held a professorship in the Punjab University, at Lahore. In the administrative grade he served first as principal medical officer of the Presidency District, Calcutta, and afterwards as inspector-general of civil hospitals in Assam. He was made C.B.E. for his services in the war. He was the author of the *Assam Pharmacopoeia* (1900), and of *History of the Families of Calthrop and Calthorpe* (1905).

Obituary

WILLIAM HENRY WELCH, M.D., LL.D.

Formerly Professor of Pathology and of the History of Medicine,
Johns Hopkins University

The death, on April 30th, in the Johns Hopkins Hospital, Baltimore, some months after a severe operation, of Professor W. H. Welch removes a great figure in scientific medicine.

The descendant in the direct line of other medical men, he was born on April 8th, 1850, at Norfolk, Connecticut, in a house which eighty years later was distinguished by a plaque inscribed: "To Dr. William Henry Welch: Dean of American Medicine." Graduating with classical honours at Yale in 1870, he entered the medical school of the College of Physicians and Surgeons, Columbia University, in 1871, and became M.D. in 1875, serving

William H. Welch.

After the dry-point engraving
by Alfred Hutton

as an intern at the Bellevue Hospital, before he went, in 1876, to work at Strasbourg under von Recklinghausen, at Leipzig with Ludwig, at Breslau with Cohnheim, and at Vienna under Chiari and Hebra. On his return to New York in 1879 he was made professor of pathological anatomy and general pathology at the Bellevue Medical College, and held the chair until 1884, when he was appointed the first whole-time professor of pathology at the Johns Hopkins University, Baltimore, where he remained in one capacity or another for

the next fifty years of his long life. Johns Hopkins, a Baltimore merchant and Quaker millionaire, who died on Christmas Eve, 1873, endowed "a university, for there will always be youth to teach; and a hospital, for there will always be suffering to relieve." In 1884 a provisional medical faculty was established, and Welch's chair was one of the first. He at once went to Germany to gain a thorough mastery of the rapidly developing science of bacteriology under Koch, whom he had previously met at Breslau, at Berlin, and elsewhere. In the autumn of 1885 he began research and graduate teaching in his laboratory at Baltimore, where among his co-workers and pupils were G. M. Sternberg, Walter Reed of yellow fever fame, W. S. Halsted, W. G. Councilman, and Simon Flexner. Financial difficulties, however, delayed the opening of the Johns Hopkins Hospital until 1889, and of the undergraduate medical school till 1893. Welch had much say, together with J. S. Billings, the medical adviser, in the selection of the clinical professors—William Osler, W. S. Halsted, and Howard A. Kelly—who, like Welch, were all under the age of 40, and later appeared in J. S. Sargent's portrait of "The Four Doctors" (1905), which now adorns the W. H. Welch Medical Library. Welch became pathologist-in-chief to the hospital, and was the first dean of the medical school for five years (1893-8).

As a pathologist he had the broadest possible outlook, and covered the whole field of this biological science. Thus, to give a few examples only of his enormous output—his Bibliography in 1917 contained 335 items—he worked on haemorrhagic infarction, embolism and thromboses, discovered the *Staphylococcus epidermidis albus* and the *Bacillus aerogenes capsulatus*, both in 1892, and carried

out experimental work on pulmonary oedema (1878) and on glomerulonephritis (1886). His pupils filled pathological chairs in many American universities; and not only in the New World, for the Emeritus Quick professor of biology at Cambridge, G. H. F. Nuttall, worked in his laboratory forty-four years ago. His pupils have often arisen to call him blessed and express their deep debt of admiration and lasting affection—for example, on the more or less public occasions of the twenty-fifth anniversary in 1900 of his doctorate, when he was presented with a *Festschrift*, and on his seventieth and eightieth birthdays.

As an able administrator and shrewd judge of men and their capacities, so that his recommendations for appointments were eminently successful, he was much in demand by scientific bodies connected with medical research, and freely did he give his services and sacrifice his scanty leisure. Thus he had been president of the Board of Scientific Directors of the Rockefeller Institute for Medical Research since 1901, and Carnegie trustee from 1906. On several occasions during the last decade of the last century he came to the rescue by successfully preventing legislation against animal experiments. In preventive medicine he long took a leading part; in 1897 he became president of the Maryland Public Health Association, at a time when action was sorely needed, and remained in office for a quarter of a century; in 1903 he was a member of the subcommittee of the Committee of Fifty to investigate the liquor problem, and wrote the report on the pathological effects of alcohol; and in 1916 he resigned the chair of pathology at Johns Hopkins University to become director of the important School of Hygiene and Public Health at Baltimore.

Welch was a man of wide sympathies and culture, and years ago was described by Osler as "extraordinarily well versed in the history of medicine, and, apart from technical knowledge, having a fund of information on all conceivable topics—from bridge to baseball, from Horace to Herrick." He was a bibliophile who also knew the contents of books with extreme accuracy, and his interest in medical history was not the hobby of an old man, for he was in 1889 the first president of the Johns Hopkins Medical Historical Club. In 1926 he was elected to the new chair of medical history in the Johns Hopkins University, and at once set out to journey over Europe in order to buy books. Six years later he resigned, and was succeeded by Professor Henry Sigerist. The W. H. Welch Medical Library, in charge of Lieut.-Colonel F. H. Garrison, and the Osler Library at McGill University, Montreal, presided over by Dr. W. W. Francis, were by a happy coincidence dedicated in the same year (1930).

The revolution in medicine that has taken place in North America in the last half-century should be mainly ascribed, as is most justly due, to the two great leaders and friends of the Johns Hopkins School—Osler and Welch—who in so many ways resembled each other, especially in their humanity, genius for friendship, wide vision, and entire unselfishness. Welch was a bachelor, a clubbable soul much given to hospitality, and a charming companion. Honours, entirely unsought, crowded upon him: he was an original member in 1886 of the Association of American Physicians, then limited to a hundred, its president in 1901, and was elected an honorary member in 1913; there is now one original member living. He was President of the American Medical Association in 1910, and of other societies too numerous to mention. He was elected Foreign Corresponding Member of the British Medical Association in 1932, was an honorary Fellow of many scientific bodies in Europe, and was the recipient of a number of foreign decorations.

HUMPHRY ROLLESTON.

JAMES HAIG FERGUSON, M.D., LL.D.,
F.R.C.P.Ed., F.R.C.S.Ed.

The death took place on May 2nd, at his residence in Coates Crescent, Edinburgh, of Dr. James Haig Ferguson, one of the best-known gynaecologists in this country. He had been in failing health for a considerable time.

He was born in Edinburgh in 1862, his father being the minister of Fossoway Parish Church, Perthshire. After a preliminary education at the Collegiate School, Edinburgh, Haig Ferguson entered upon a medical course at Edinburgh University, where he graduated M.B., C.M. in 1884. In the same year he became a Member of the Royal College of Surgeons of England. After a period spent as resident physician with the late Dr. Claude Muirhead in the Royal Infirmary, Edinburgh, he also acted as resident physician in the Royal Hospital for Sick Children, and then took up gynaecology as a specialty and was appointed clinical tutor in the department for diseases of women. He joined the Royal College of Physicians of Edinburgh as a Member in 1887, proceeding to its Fellowship in 1889, and he also joined the Royal College of Surgeons of Edinburgh as a Fellow in 1902. In 1890 he obtained with honours the M.D. degree of Edinburgh University. In April, 1896, he was appointed assistant gynaecologist on the staff of the Royal Infirmary of Edinburgh, and in 1921 he was promoted to the charge of a gynaecological ward. Retiring under the age limit in 1927, he was appointed consulting gynaecologist to this institution. In the following year

his great services to the University and Medical School of Edinburgh were recognized by the University, which conferred upon him the honorary degree of LL.D.

For many years Dr. Haig Ferguson had conducted a large family practice in addition to his specialty, but on taking charge of wards he limited himself to work as a consulting and operating gynaecologist and obstetrician. His post in the Royal Infirmary carried with it that of lecturer in clinical gynaecology in the University of Edinburgh, and he also lectured on midwifery and diseases of women in the School of Medicine of the Royal Colleges. For a long period he was also gynaecologist to Leith Hospital and physician to the Royal Maternity Hospital, Edinburgh. He had acted as examiner in midwifery both in the University of Edinburgh and in that of Aberdeen. Immediately after graduation Dr. Haig Ferguson had been elected one of the annual presidents of the Royal Medical Society of Edinburgh, and he later served a term as president of the Edinburgh Obstetrical Society. At the time of his death he had been a member of the British Medical Association for forty-eight years, and his long connexion with the Association, as well as his eminence in his chosen specialty, was recognized by his election as president of the Section of Obstetrics and Gynaecology at the annual meeting of the Association held at Edinburgh in 1927. He filled the office of president of the Royal College of Surgeons of Edinburgh in 1929-31. His outstanding position among Scottish obstetricians and his judicious powers in the conduct of business were recognized by his appointment as chairman of the Central Midwives Board for Scotland, a post which he held at the time of his death. He was also vice-president of the Scottish branch of the Queen Victoria Jubilee Institute of District Nursing, and, as chairman of the Governing Board of the School of Medicine of the Royal Edinburgh

Colleges, he took a deep interest in the education of medical students.

Dr. Haig Ferguson had written several textbooks, which enjoyed a great measure of success. In 1889, along with the late Dr. F. W. N. Haultain, he published a *Handbook of Obstetric Nursing*, which had gone into a fifth edition in 1906. In 1923, along with Drs. Munro Kerr, James Young, and Hendry, he published *A Combined Text-book of Obstetrics and Gynaecology*, which went into a second edition ten years later. He also contributed numerous articles dealing with obstetrics and gynaecology to medical literature, such as the article on "Puerperal Affections of Breasts and Nipples," in the *Encyclopaedia Medica*, and one on "Abdominal Hysterectomy for Acute Puerperal Metritis," in the *Transactions of the Obstetrical Society of Edinburgh*, 1906.

As a practitioner Dr. Haig Ferguson was distinguished for his never-failing kindness, courtesy, and sympathy. These qualities had endeared him greatly both to his numerous patients and to his colleagues. He was a hard and consistent worker in the practice of his profession, sometimes even to the detriment of his own health. In his specialty he was recognized as the final authority in Edinburgh, and it was a matter of great regret to his many friends and admirers that he never occupied the professorial chair of midwifery in Edinburgh University. He was recognized as a skilful operator in gynaecology, and his influence on the practice of obstetrics was extensive, through both his writings and his teaching. For obstetric nursing in Scotland he had done a great deal during his long tenure of the chair of the Central Midwives Board for Scotland, and much of the success which attended the work of this Board was due to his wise foresight and judicious counsel.

Although constantly engaged in the cares of practice Dr. Haig Ferguson was a member of the King's Bodyguard of Scottish Archers, and took a great interest in the archery competitions of that body. He was also a keen fisher and hill climber when occasion offered during his holidays. In 1889 he married a daughter of the late Sir Patrick Heron-Watson, a noted figure in Edinburgh medicine. He is survived by his widow and by one son and three daughters.

A funeral service was held in St. George's Parish Church on May 4th, which was attended by a large congregation, including many members of the medical profession, and by representatives from the Royal Colleges of Physicians and Surgeons, Edinburgh, the School of Medicine of the Royal Colleges, Edinburgh, the Royal Edinburgh Hospital for Sick Children, the Central Midwives Board for Scotland, and a detachment of nurses from the Queen's Institute of District Nursing. The interment took place in the Dean Cemetery, where the ceremony was private.

Dr. JAMES YOUNG writes:

Dr. Haig Ferguson's death has removed from our midst the doyen of Edinburgh obstetrics and a very gracious personality. Great as were his gifts and his service, to his friends he will remain rather as a presence which was precious in its possession of those qualities of heart and mind that are above the ordinary world's measurement. His handsome figure, his gentle and courteous manner to rich and poor alike, and his kindly humour are among those things that to his patients, students, and friends scattered over the world fill in the memory of a great doctor and of a character of singular charm. His presence warmed because it was itself suffused with those rich warm springs that flowed from a nature peculiarly sensitive in its sympathy and understanding.

Naturally retiring and almost timid in temperament, Haig Ferguson was hesitating and sometimes ineffective as a speaker, and this handicapped him when he was

called upon to engage in public affairs. He so controlled these defects of temperament, however, that in his later years he occupied, with success and acceptance, public posts of high responsibility. He was chairman of the Central Midwives Board for Scotland and president of the Royal College of Surgeons, besides holding managerial positions in the Royal Infirmary, the Royal Hospital for Sick Children, and Donaldson's Hospital School.

Haig Ferguson had a large obstetric and gynaecological practice, and this, with his hospital appointments, so engrossed his time that he left himself little leisure. He was an indefatigable worker, and his precision in regard to such accompaniments of an active professional life as correspondence and punctuality were at once an example and a disciplinary test to his assistants and hospital staff. Throughout the active years of his life he was fortunate in the possession of a vigorous constitution, which withstood the many strains imposed upon it by the exigencies of an active obstetric practice.

J. CAMPBELL MCCLURE, M.D.

Senior Physician to the French Hospital, London

By the death of Dr. J. Campbell McClure, which occurred with tragic suddenness on May 2nd, four days after the wedding of one of his sons, the French Hospital and colony in London have been deprived of a notable personality.

James Campbell McClure was born in February, 1873. A graduate of the University of Glasgow, he remained in that city for ten years as physician to out-patients in the Western Infirmary and Sick Children's Hospital, and as assistant to the professor of medicine. He also held an appointment at the Belvidere Fever Hospital. Migrating to London, he became in course of time physician to the French Hospital and to Margaret Street Hospital for Consumption. In addition he held several other minor appointments.

The author of many publications, his most valuable contribution to medical literature was probably a handbook on the infectious fevers, the fruit of his early experience at Belvidere, the readable and practical nature of which rendered it, in its time, a favourite with students. A good knowledge of fevers is an excellent foundation for general medicine; but McClure's interest widened to include also balneology and climatology, his active attention to which gained him the office of president of that section of the Royal Society of Medicine. With this wide and varied grounding, McClure developed into a general physician possessed of unusual skill in diagnosis. Shrewd, downright, and practical by nature, he was little liable to follow any will-o'-the-wisp in tracking symptoms to their origin, and yet little escaped his keen observation. In later life this acumen grew to that point of skill when knowledge and experience combine to form a flair or intuition as nearly faultless in its conclusions and decisions as any human judgement can be. But McClure's firm grasp on actuality would have left him dissatisfied with the merely diagnostic side of medicine. His knowledge of therapeutics was deep. Again, however, his strong common sense and balance enabled him to form a therapeutic repertory that was reliable as well as varied.

Any account of Campbell McClure's professional life, however brief, would be culpably incomplete if no reference were made to his devoted services to the French Hospital. In his twenty-one years as physician he has seen the reputation of the hospital grow until, at the present day, it has come to be the trusted resort in time of sickness not only of French and Belgians, but of the entire foreign population of London. In this great development McClure played a conspicuous part. His

services in this respect were recognized when he received the coveted award of the Legion of Honour, of which he was Chevalier, and of the Palmes en Or of the Order of the Crown of Belgium. But these official decorations were merely the outward sign of his high reputation as a hard-working and successful physician in the foreign world of the metropolis, where his loss will be long and deeply felt.

Much sympathy is expressed for his widow, a daughter of the Taylorian Reader in French in the University of Oxford, and for his family.

T. R. LLEWELLYN, M.R.C.S., L.R.C.P.

We regret to announce the death on April 20th, at his home in Penarth, of Dr. Thomas Richard Llewellyn, regional medical officer under the Welsh Board of Health. Dr. Llewellyn, who was born in 1868 in Penygraig, the son of a well-known colliery manager, studied medicine at University College, London, and qualified M.R.C.S., L.R.C.P. in 1894. He started practice in his native town of Penygraig, where he remained for thirty years. During this time he took a prominent part in colliery rescue work, and identified himself with local public affairs; for three years he served as a member of the Glamorgan County Council. In 1920 he relinquished private practice to take up an appointment as regional medical officer of the Welsh Board of Health. Dr. Llewellyn was predeceased by his wife a few months ago, and is survived by one son and two daughters.

Dr. D. LLEWELLYN WILLIAMS writes: The death of Dr. T. R. Llewellyn on April 20th, just as he was about to retire, is a sad loss to the insurance medical service in South Wales. He relinquished an extensive medical practice in the Rhondda Valley to join the regional medical service on its inception in 1920; he acted as regional medical officer for East Glamorgan and Monmouthshire. Dr. Llewellyn was a man of strong personality, and his high ideals of medical service called for the best from insurance practitioners in his region. He was always frank and straightforward, and had a somewhat courtly manner; no one could take liberties with him, but those who tried to do their best found in him a good friend. His wide clinical experience in a large colliery practice before and after the passing of the National Insurance Act enabled him to perform his duties as medical referee with great satisfaction, both to approved societies and to insurance medical practitioners. Much of the improvement in the clinical aspect of insurance practice is due to his efforts. The Welsh Board of Health has lost a loyal and efficient officer, and his medical colleagues a true and faithful friend.

The death of FRANK A. SPREAT, F.R.C.S., which occurred on April 24th, came as a great shock to his medical colleagues and many friends. Although it was known that he had not been in good health for some time, his death occurred very suddenly. Frank Arthur Spreat, who was 72 years of age, was educated at the Aldenham School and St. Bartholomew's Hospital. Qualifying in 1884, he settled in practice in Friern Barnet very shortly afterwards, and for a good many years was one of the best-known practitioners in North London. Dr. Spreat was a man of most unbounded energy, and performed the somewhat remarkable feat of passing his first and final Fellowship examinations of the Royal College of Surgeons after the age of 40, and also taking his D.P.H. whilst in general practice. During the greater part of his professional life he made a point of attending one of the teaching hospitals one day a week, and even when he was nearly 60 years of age he still continued to take special courses in clinical work. Dr. Spreat held many public appointments. He was medical officer and public vaccinator for the Friern Barnet district, medical officer for the maternity and child welfare centres under the Middlesex County Council, and he was also medical officer to the

Post Office. For many years he was medical officer of health to the Friern Barnet district, during which time he kept himself thoroughly conversant with the ever-increasing public health problems, and was the means of instituting many admirable reforms. For over forty years he was a member of the British Medical Association, in which he had always taken the greatest interest, and had been chairman of the Finchley Division. Dr. Spreat was greatly respected by all the medical men with whom he came into contact, and his loss will be much felt by his fellow practitioners. He married Miss Edith Hulke, daughter of the late Dr. Hulke of Deal, and she survives him with a son and a daughter. His younger son he lost in the war.

Those who knew Dr. IDRIS DAVID EVANS will greatly regret to hear of his sudden death, on May 3rd, at his home in Prebend Mansions, Chiswick. He had recently undergone a successful operation and was apparently in perfect health. Dr. Evans, who was 43 years of age, qualified in 1914, and took his M.D. (Durham) in 1917, having received his medical education at Newcastle-upon-Tyne. He served as major in the R.A.M.C. during the war. He had lived for a considerable time at Cardiff, and served as medical assessor to the Pensions Appeal Tribunal. Called to the Bar at Gray's Inn, he had recently become interested in coroners' work, obtaining the appointment of deputy coroner for Central London last October. During his tenure of this office he held the inquest upon the body of a cabaret artist who died as a result of taking drugs for slimming. It was on this occasion that he called attention to the fact that drugs of the nitrophenol group are accessible to the general public, and legislation has since been introduced limiting the sale of these drugs. Dr. Evans leaves a widow and one son.

Universities and Colleges

UNIVERSITY OF OXFORD

The Board of the Faculty of Medicine has elected R. E. Havard, D.M., Queen's College, to the Schorstein Research Fellowship for 1934.

UNIVERSITY OF CAMBRIDGE

Two public lectures will be given on Monday and Tuesday, May 14th and 15th, at 5 p.m., in the new lecture theatre of the Department of Physiology, by Dr. Alfred Adler of Vienna. The subject of the first lecture is the principles of individual psychology; of the second, active and passive personalities.

The titles of the degrees of M.B., B.Chir., have been conferred on A. H. Field (Newham College).

The following candidates have been approved at the examination indicated:

DIPLOMA IN MEDICAL RADIOLOGY AND ELECTROLOGY.—L. R. B. Burt, E. W. H. Shawcross, B. W. Windeyer.

UNIVERSITY OF LONDON

The Court, at its meeting on May 2nd, learnt with gratification of grants from two more of the city companies—namely, the Fletchers and Pewsters. These benefactions will be applied towards meeting the cost of the Ceremonial Hall, to be built on the University site in Bloomsbury. A very cordial vote of thanks was passed to the Essex Education Committee and County Council for increasing their grant to the University for 1934-5 from £1,000 to £1,500.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE

D.P.H. Course: Fishmongers' Studentship

The 1934-5 course of study, which qualifies students to sit for the University of London Diploma in Public Health, covers a period of nine calendar months' whole-time work, commencing on October 1st, 1934. The fee (54 guineas) covers the cost of the ordinary lectures and demonstrations, visits to centres of public health interest, the necessary practical work with the medical officer of health, and instruction in infectious diseases.

One place will be allotted, without fees, after open competition on June 28th and 29th, the successful candidate being awarded the Fishmongers' Company Studentship. Applications to compete for this studentship must be sent in by June 18th. Inquiries in regard to this course or the courses of study in bacteriology, epidemiology and vital statistics,

industrial psychology, tropical medicine and hygiene, etc., should be addressed to the Secretary, London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, W.C.1.

Langley Memorial Prize

This prize, of the approximate value of £21, is open to competition among officers of the West African Medical Staff, whether on the active list or retired list. The award will be made in respect of the best paper on one of the following subjects (special consideration to be given to original work): (a) Tropical Medicine or Surgery. (b) Tropical Hygiene and Sanitation. (c) Tropical Entomology and Parasitology. Papers must be delivered to the Secretary, London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, W.C.1, before October 1st, 1934, from whom further particulars can be obtained on application.

UNIVERSITY COLLEGE, LONDON

The Fellows of University College, London, held their annual dinner at the College on April 30th, on which date the first stone of University College was laid by H.R.H. the Duke of Sussex in 1827. Sir John Rose Bradford, Bart., M.D., F.R.S., Chairman of the College Committee, presided. Before dinner those who had been recently elected were admitted to the Honorary Fellowship or Fellowship by the chairman. The new Honorary Fellows are: Emeritus Professor Karl Pearson, who occupied the Chair of Applied Mathematics and Mechanics from 1884 to 1911 and the Galton Chair of Eugenics from 1911 to 1933; and Emeritus Professor Sir Flinders Petrie, who was Edwards Professor of Egyptology from 1893 to 1933—admitted *in absentia*. The new Fellows are Miss Edith C. Batho, Professor B. Ifor Evans, Dr. Edward Mallett, Mr. Harold James Page, and Dr. Alan Sterling Parkes.

UNIVERSITY OF BIRMINGHAM

Dr. Stuart McDonald has been appointed lecturer in pathology in place of Dr. F. W. M. Lamb, resigned.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

At a quarterly meeting of the Royal College of Physicians of Edinburgh, held on May 1st, with the president, Dr. Edwin Bramwell in the chair, Dr. Francis William Murray Cunningham, D.S.O. (Hove), took his seat as a Fellow, and Dr. William Lindsay Kinnear (Dundee), Major James Henry Barrett, I.M.S., and Dr. David Rhys Lewis (Swansea) were elected Fellows.

Dr. Robert Thinn was re-elected a representative of the College on the Conjoint Committee of Management of the Triple Qualification.

It was announced that the Cullen Prize had been awarded equally between Sir Frederick Kay Menzies, K.B.E., and Lieut.-Colonel A. G. McKendrick.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

The House of Lords this week discussed a Parliamentary (Reform) Bill introduced by Lord Salisbury. Lord Hailsham said reform of the House of Lords would have to be a Government measure, but that the Government had not decided to propose it.

The House of Commons took the Unemployment Bill on report. Earlier a new clause was proposed by Mr. J. J. Lawson to extend unemployment insurance to non-manual workers with salaries of less than £500 a year. Sir Henry Betterton promised to ask the Unemployment Statutory Committee to consider the proposal. The new clause was defeated.

The Workmen's Compensation (Coal Mines) Bill and Water Supplies (Exceptional Shortage) Bill were read a second time, and the Firearms Act Amendment Bill a third time by the House of Lords on May 2nd. The Protection of Animals Bill was read a second time by the Lords on May 3rd.

In the House of Commons, on May 4th, the Cotton Manufacturing Industry (Temporary Provisions) Bill was read a first time.

The Hotels and Restaurants Bill was withdrawn on May 2nd. The Licensing (Standardization of Hours) Bill was set down for report in the Commons on May 4th, but was not reached, and no further progress with it is expected this session.

On May 7th the Water Supplies (Exceptional Shortage) Bill passed through committee.

In the House of Lords on May 7th the Registration of Births, Deaths, and Marriages (Scotland) (Amendment) Bill was read a second time.

Sir FRANCIS FREMANTLE moved the second reading of the Contraceptives Bill in the House of Commons on May 7th. Objection was taken to the motion, and the Bill was set down again for that day week.

Warren Fisher Report and Dental Services

On May 8th Captain ELLISTON asked if the recommendations of the Warren Fisher report could be extended to include dental officers as submitted in a memorandum by the British Dental Association. Mr. HORE-BELISHA said that the committee on the medical branches of the Defence Services suggested that some of their proposals in regard to the medical services might with advantage be applied to the dental services. He understood representations had been made by the British Dental Association to the Defence Departments, and that this question was now under consideration.

Milk-borne Diseases Report

On May 8th Brigadier-General Brown asked the Prime Minister if he would publish the report of the scientific committee appointed by the Economic Advisory Council to consider the incidence of milk-borne diseases, and if steps would be taken to submit its findings to agricultural interests, as well as to medical authorities, before any legislative action on it was taken. Mr. RAMSAY MACDONALD replied that the committee's report had just been received, and it had not yet been possible to consider the question of its publication. The interests of every section of the population would be carefully borne in mind by the Government when it reviewed the conclusions of the committee. Mr. LAMBERT asked if Mr. MacDonald would, if possible, publish the report. Mr. MacDonald said that as soon as he had had an opportunity of reading it he would decide whether the report should be published or not. All the bias was in favour of publication. Lieut.-Colonel TROYTE asked if the Council considered that diseases were brought in by butter from foreign countries. Mr. MacDonald said he would imagine not, but he did not know, as he had not had time to read the report.

Slum Clearance in Scotland.—Mr. SKELTON, replying on May 1st to Mr. Neil Maclean, said that information as to the total number of unfit houses to be cleared in Scotland was not available, but according to the programmes for the five years 1934-8, submitted by 208 out of 228 housing authorities in Scotland, it was estimated that 59,774 houses were required to replace unfit ones, and that 42,948 new houses, or 72 per cent. of the estimated requirements, would be erected for this purpose. Neither of these figures was final.

Small-pox at Blackburn: Error in Diagnosis.—On May 1st Sir HILTON YOUNG told Mr. Groves that the first case of small-pox in the recent outbreak at Blackburn, which proved fatal the day after admission to hospital, had been wrongly diagnosed. On the death certificate the death was attributed to (a) heart failure, (b) acute toxæmia, (c) varicella. The death had been classed to small-pox.

Unemployed and Old Age Pensions.—On May 1st Mr. SHAKESPEARE informed Mr. Batey that nothing had arisen to reopen the question of legislation to amend the National Health Insurance Act, 1932, so as to restore medical benefit and old age pension benefit at 65 years of age to unemployed workmen. The position under the Contributory Pensions Acts of the insured person who had suffered from prolonged unemployment was fully safeguarded up to the end of 1935.

Disablement Due to Silicosis.—Sir JOHN GILMOUR told Mr. Rhys Davies, on May 2nd, that since June 1st, 1931, when the medical board was appointed, up to April 30th, 1934, there had been 437 coal miners certified by the board as disabled through silicosis; 129 of these were certified as partially disabled. Earlier comparable figures were not available. From February 1st, 1929, when the Various Industries (Silicosis) Scheme came into operation, up to the end of 1932, compensation was paid in 143 cases of disablement. There were

a large number of cases in 1933, but the precise figure was not yet available. The number of deaths certified since January 1st, 1934, was fourteen.

Explosions of Firedamp.—Colonel COLVILLE told Mr. Grundy, on May 3rd, that the number of fatal accidents caused by explosions of firedamp or coal dust in mines in 1932 was thirteen, resulting in sixty-nine deaths. In 1933 there were eight accidents and eight deaths. In one of these cases proceedings were taken against the owners, agent, manager, and under-manager, who were charged with contraventions of Section 29 and Section 34 of the Coal Mines Act, 1911. He could not undertake to bring in legislation to make it a criminal offence against the management, directors, and owners where an explosion took place in any pit with which they were connected. Every explosion was investigated.

Infant Mortality in Kensington.—Sir HILTON YOUNG told Mr. West, on May 5th, that the infant mortality rates in South Kensington, North Kensington, and the Norland Ward of Kensington would be published in the annual report of the medical officer of health for 1933. Mr. West asserted that the death rate in the Norland Ward of Kensington was 140 per 1,000, or twice as high as that of Poplar.

House Erection in England and Wales.—Mr. SHAKESPEARE informed Mr. Mitcheson on May 8th that the total number of houses built in England and Wales (excluding houses of a rateable value exceeding £78, or £105 in Greater London) during the half-year ended March 31st, 1934, was 153,299, of which 120,781 were built by private enterprise without State assistance. The highest corresponding total during any previous half-year ending March 31st was 111,066 for the half-year ended March 31st, 1927.

Medical Treatment of School Children.—Mr. RAMSBOTHAM states that the amount recovered from parents in respect of the medical treatment of children attending public elementary schools during the financial year 1931-2, the latest period for which complete audited accounts of local education authorities are yet available, was £69,370.

Imported Milk Products.—Mr. SHAKESPEARE stated recently that most imported milk products were made from pasteurized milk or cream. If the product was in liquid form the Ministry had complete powers and regulations with regard to bacteriological examination. As regards non-liquid products, the Minister of Health was informed that there was no danger to health.

Milk Supplied to Prisons, etc.—Colonel HENEAGE asked Sir John Gilmour, on April 26th, whether the contracts of the institutions under his control required the purchase of Certified, Grade A, or ordinary standard milk. Sir JOHN GILMOUR answered that, as regards schools approved under the Children and Young Persons Act, 1933, some provided themselves with milk from their own farms; the others purchased ordinary standard milk. Milk contracts for prisons and Borstal institutions required the supply of fresh genuine whole milk, the conditions being substantially the same as those laid down by the Milk Marketing Board. Certified milk and Grade A milk were not used.

Physical Training among Prisoners.—Sir JOHN GILMOUR states that men who are physically fit receive in the larger prisons physical training daily under the supervision of qualified officers, unless they are employed on outdoor work of a kind which makes such exercises less necessary. Gymnastic classes under qualified instructors are held in the evenings at practically all establishments, except those where the age or the physical condition of the prisoners makes it undesirable. In women's establishments the numbers suitable for physical training are small, but classes are held where possible, and there is a physical-training instructress at Aylesbury Borstal Institution.

Notes in Brief

At the end of June, 1933, 2,398,000 persons between the ages of 16 and 64 were registered for unemployment insurance in the London division, which corresponds approximately with the Greater London area.

At March 31st, 1933, 2,213,000 persons in the United Kingdom were in receipt of old age pensions.

Sir John Gilmour is not prepared to propose legislation giving magistrates the power to order flogging as a penalty in cases of cruelty to animals.

Medical News

The eighth annual Macalister Lecture will be delivered by Dr. Robert Hutchison on "Praise and Dispraise of Doctors" at the National Temperance Hospital, Hampstead Road, N.W., on Thursday, June 21st, at 9 p.m. All medical practitioners and their friends are invited.

The fifteenth Maudsley Lecture before the Royal Medico-Psychological Association will be delivered by Lord Macmillan, on "The Professional Mind," at 26, Portland Place, W., on Thursday, May 17th, at 3 p.m. Admission without ticket.

Dr. J. B. Orr will deliver a Chadwick Public Lecture at the Royal United Service Institution, Whitehall, S.W., on Tuesday, May 29th, at 5.30 p.m. His subject will be "The National Food Supply and Public Health." Admission free, without ticket.

The next meeting of the Royal Microscopical Society will be held at B.M.A. House, Tavistock Square, W.C., on Wednesday, May 16th, at 5.30 p.m., when the curator, Mr. W. E. Watson Baker, will exhibit and describe the Nachet binocular microscope recently acquired, and papers will be read by Dr. E. S. Horning and Professor C. Leonard Huskins.

Dr. Alfred Adler will address a special meeting of the Medical Society of Individual Psychology at 11, Chandos Street, W., on Thursday, May 17th, at 8.30 p.m.

At the annual general meeting of the Chelsea Clinical Society to be held at the Hotel Rembrandt, Thurlow Place, S.W., on Tuesday, May 15th, at 8.30 p.m., Squadron Leader P. C. Livingstone will open a discussion with a paper entitled "Ophthalmic Notes on the Air Force Pilot Over-seas." The meeting will be preceded by dinner at 7.30 p.m.

The subject of Sir Henry Lyons's presidential address before the Institute of Physics is "Physics and Science Museums." It will be given at the Royal Institution, 21, Albemarle Street, on Tuesday, May 15th, at 5.15 p.m., and tickets may be had from the secretary, Institute of Physics, 1, Lowther Gardens, Exhibition Road, S.W.7.

The next monthly clinical meeting for medical practitioners will be held at the Hospital for Epilepsy and Paralysis, Maida Vale, W., on Thursday, May 24th, at 3 p.m., when Dr. W. G. Wyllie will demonstrate. Tea will be provided. Those intending to be present are asked to send a card to the secretary.

The Glasgow University Club, London, will dine at the Trocadero Restaurant, Piccadilly, on Friday, May 25th, at 7.15 for 7.30 p.m. Professor Sir Robert Muir, F.R.S., is to be in the chair. Any Glasgow University men who, though not members of the club, desire to attend are requested to communicate with the honorary secretaries, 62, Harley House, N.W.1.

The House of the Royal Society of Medicine (1, Wimpole Street, W.) will be closed from Saturday, May 19th, to Monday, May 21st, both days inclusive.

The Fellowship of Medicine (1, Wimpole Street, W.) announces that Dr. Clark-Kennedy will give a lecture-demonstration on anginal pain on May 15th at 2.30 p.m. The lecture on May 29th will deal with functional heart-disease. Forthcoming arrangements include a week-end course in diseases of the chest at the Brompton Hospital, all-day, May 26th and 27th; a week's course in chest diseases at the City of London Hospital, Victoria Park, from May 28th to June 2nd; a fortnight's course in gynaecology at the Chelsea Hospital, May 28th to June 9th; and a month's course in venereal disease at the London Lock Hospital, May 28th to June 23rd. A week-end course in medicine and surgery has been arranged for June 2nd and 3rd at St. Mary's Hospital, Plaistow. A panel of teachers provides daily individual clinics in various branches of medicine and surgery.

A conference of the British Health Resorts Association is being held this week-end at Harrogate concurrently

with the annual general meeting of the Physical Medicine Section of the Royal Society of Medicine. On Saturday morning Professor Langdon Brown opens a discussion on the use of spas in diseases of the liver, and in the afternoon Dr. S. E. Dore opens a discussion on the spa treatment of skin diseases.

The thirteenth annual conference of the Federation of Cremation Authorities in Great Britain will be held in conjunction with the annual conference of the National Association of Cemetery and Crematorium Superintendents at Birmingham from June 23th to 28th. Papers on various subjects connected with the disposition of the dead will be presented, including contributions from Sir John Robertson and Sir Gilbert Barling, and will be followed by discussion. The meetings of the conference will be held in the Council House, Birmingham, with the exception of the Wednesday meeting, which will be held in the Town Hall, Sutton Coldfield. The Lord Mayor, Alderman H. E. Goodby, J.P., will preside at the opening session.

We are asked to announce that the Savill Prize, value £15, which is offered biennially by the West End Hospital for Nervous Diseases, will be awarded this year. Candidates, who should be post-graduate students, are required to write a thesis on a neurological subject of their choice, which subject must be submitted for approval not later than May 31st; they must also have attended the practice of the hospital on at least ten occasions. Theses must be received not later than November 30th, and are accepted only on the condition that they shall not be published except with the written consent of the examiners. Further particulars may be obtained from the secretary of the hospital, 73, Welbeck Street, W.1.

The issue of the *Wiener medizinische Wochenschrift* for April 21st is dedicated to Professor Adolf Lorenz, the well-known orthopaedic surgeon of Vienna, who celebrated his 80th birthday on that date.

The issue of *Paris Médical* for April 28th contains a French translation, by Dr. A. Baudoin, of Argyll Robertson's paper in the *Edinburgh Medical Journal* of December, 1869, describing the ocular changes to which his name has been attached.

The May issue of *The Practitioner* includes five articles on diseases of the eye, by Dr. W. J. Adie, Mr. N. Bishop Harman, Mr. P. G. Doyne, Mr. J. Cole Marshall, and Mr. H. B. Stallard.

The Spanish Academy of Dermatology and Syphiligraphy will celebrate the twenty-fifth anniversary of its foundation on May 17th and 18th.

On April 21st Mr. John Lionel Stretton of Kidderminster, who recently completed his fiftieth year as a member of the honorary staff of the Kidderminster and District General Hospital, celebrated, with his wife, his golden wedding. He has been president of the hospital staff for the last ten years, and has served as chairman of the County of Worcester Local Medical and Panel Committee for twenty years.

May 14th is the 200th anniversary of the death of the physician and chemist Georg Ernst Stahl, the founder of the theory of phlogiston and animism.

The Pathological Museum in connexion with the Annual Meeting of the British Medical Association at Bournemouth next July will comprise (a) exhibits bearing on discussions and papers in the Sections; (b) specimens and illustrations bearing upon recent research work; (c) instruments relating to clinical diagnosis and pathological investigation; (d) individual specimens of special interest, or a series illustrating some particular subject. It is also hoped to have exhibits relating to neurology and to heredity and mental and physical deterioration, and a series of x-ray and other photographs. The committee is anxious for the co-operation of pathologists and others in securing specimens of medical interest on the lines indicated above. Offers of assistance may be sent to the honorary secretary of the Museum Committee, Dr. C. G. H. Morse, Room 30, Town Hall, Bournemouth, to whom specimens should be forwarded by July 9th.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR OF THE *BRITISH MEDICAL JOURNAL*, *Aithology Westcent, London.*

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate Westcent, London.*

MEDICAL SECRETARY, *Mediscera Westcent, London.*

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Daclins, Dublin*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

Thickened Skin after X Rays

"SUBURBAN G.P." writes: A young lady had several x-ray applications to the palm of her right hand, some twelve years ago, for "skin trouble." The skin exposed to this treatment has now become thickened and hardened (? hyperkeratosis) and roughened. Can any reader suggest a suitable application or treatment likely to counteract the condition?

Movement of Needles in the Tissues

"SCEPTIC" (Northampton) writes: Until quite recently I have believed that needles, unless actually deposited within a hollow viscus, such as a blood vessel, tendon sheath, or the gut, remain practically stationary. I have in the past ridiculed the anxiety of patients who present themselves with a needle in the hand, or foot, and a tourniquet placed proximally. I would be glad to know if needles so placed are able to "travel," and, if so, to what extent.

Artificial Menopause

"G. E. B." writes: The symptoms, subjective and objective, arising from the artificial menopause are, it is well known, very difficult to be dealt with by the doctor in charge of a patient after a hysterectomy and oophorectomy. My case is that of a woman aged 49, who had, previous to this operation, performed in August, 1933, menstruated regularly—it was done as a last resource to clear up a prolonged psychoneurosis with anxiety state. Pathologically it proved to be most justifiable and necessary. Can any of your readers give me assistance in clearing up the outstanding physical symptoms—that is, profuse and regular night sweats, which drench the patient and wake her three or four times every night? She has had a long course of the various brands of ovarian extracts, given orally and intramuscularly up to 1,000 mouse units on alternate days. Also full doses of atropine and zinc oxide at bedtime. Any other possible cause of the sweating has been carefully excluded.

Disinfection of Room used by Cancer Patient

"A. W." writes: A lady who has had two operations for cancer of the breast, and has been apparently successfully treated for a third appearance, visits friends from time to time. Is it safe, after her departure, for others to occupy the room without disinfection, or should the mattress, at any rate, be fumigated? There are such conflicting opinions on the subject.

Income Tax

Retirement from Partnership—Cash Basis

"M.B." writes: The basis of our partnership income tax has been on the cash receipts each year up to the end of our financial year. If I retire at the end, say, of next September, what income tax would I be liable for in January and July, 1935?

* If £x is "M.B.'s" share of the partnership assessment for 1934-5, then if he retires as from September 30th,

1934, he will be liable to assessment on 1/2 of £x only, and he will not be liable to tax on the cash receipts which have not entered into the calculation of the assessments—that is, to those subsequent to September 30th, 1933. The "cash receipts" merely supply a convenient means of calculating the gross income of the practice, and tax payable for the year 1934-5 is in respect of the income of that year. The individuals concerned, including the incoming partner (if any), can, on a unanimous election, claim to have the practice regarded as ceasing and restarting at September 30th, 1934, but that seldom operates to the benefit of the outgoing partner.

LETTERS, NOTES, ETC.

Maternal Mortality Among Primitive People

Dr. KATHLEEN VAUGHAN writes: Both Dr. T. L. Paget (*Journal*, April 7th, p. 644), and Dr. R. B. Michener (*Journal*, November 18th, 1933, p. 944) tell us of native races in New Zealand and in Africa who have great trouble in childbirth. The Maoris are more or less civilized, and their teeth, as Dr. Paget tells us, are defective. The Africans live in a reserve; therefore they are presumably not under natural conditions, and one would like to know more about their teeth. If one reads the Carnegie Trust Report on Maternal Mortality, 1917, one notes that easy childbirth and perfect teeth seem to go together. Does not this mean absence of rickets, and, therefore, that the brim of the pelvis is round—not only fitting the child's sub-occipito bregmatic (which engages with it in full flexion), but also containing the largest area possible to the circumference. A pelvis with a brim whose circumference is 36 cm. loses a definite percentage of its area when bent into an oval, and *this loss of area is progressive as the conjugate shortens*. One has only to read the report of the Director-General of Health, New Zealand, for 1930 to see the state of present-day Maori health—tuberculosis, cancer, goitre, trachoma, dysentery, influenza, and carious teeth are common. The one "civilized disease" they do not seem to suffer from is appendicitis—doubtless because they still squat. Granted that the Maoris are deteriorated by civilization, one understands that those of them who do not adopt European obstetric methods would be liable to have a higher maternal mortality than Europeans who do. Surely our modern obstetric methods are rendered necessary by our civilization, which deforms the pelvis, converting the round brim into an oval, with the consequent loss of area. Eldon Best described the Maori of former days as having good teeth and no difficulty in childbirth. I think life indoors has more influence on teeth, and, later on, on difficult childbirth, than we give it credit for. In other words, the school is more to blame than the tuckshop. Open-air races, such as Maoris, Africans, Indians, and, nearer home, our own people in the Islands and Highlands of Scotland, are affected at once by the indoor life necessitated by going to school, and it shows first in the teeth and later in the pelvis, with consequent trouble in childbirth. Surely it would be impossible to find with a rickety pelvis a perfect set of teeth. We are told that in Czechoslovakia an essential in a bride is perfect teeth. Experience has taught that she will make a good mother.

A Refreshing Drink

Dr. W. H. ROWTHORN (Sheffield) writes: The following will be found useful in many cases of illness, or, in fact, at any other time. Place one pound of black-currant, damson, or any other jam in a quart jug. Slice a lemon and add it to the jam. Crush well and fill up with boiling water. When cold pass the quantity required through a tea-strainer into a glass, and add soda water. It will be found very good for quenching thirst, and also makes a fine drink in hot weather.

Disclaimer

Mr. LOUIS CARNAC RIVETT, F.R.C.S., writes: In view of the publicity given in the Press to my informal talk to the Ladies' Association of Queen Charlotte's Hospital, I should like to make it quite clear that I did not know that there were reporters present, nor did I know that the proceedings were to be published.

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 42, 43, 44, 45, and 48, of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 46 and 47. A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 252.

A Lecture

ON

CANCER: WITH SPECIAL REFERENCE TO EARLY DIAGNOSIS*

BY

ROY WARD, M.B., B.S.

MEDICAL DIRECTOR AND SURGEON TO THE RADIUM INSTITUTE, LONDON

The more complicated the problem the easier it is to confuse the issues involved, and to give false values to the various factors concerned. The age-long attempt to solve the problem of cancer has resulted in the collection of a vast number of facts concerning it and in a voluminous literature, and with such a mass of information it is not difficult to make either of these mistakes. In this connexion, and before going on to discuss the general problem, I should like to stress the fact that much of this literature is concerned with the results of animal experiment, and I think that this is a field where one is likely to be misled by the reports and statements of specialized workers who pursue their efforts in a direction which is sometimes only distantly related to the problems with which we clinicians have to deal. I do not want to be misunderstood: much of the experimental work done has an importance which cannot be overestimated, and has contributed most valuably to our knowledge. That the cure of cancer may be found before its cause is a consideration that is sometimes overlooked, and, while acknowledging the debt which the clinician owes to the experimental worker, it must be remembered that the clinical interpretation of the results obtained is often difficult, and sometimes even misleading. We will confine ourselves on this occasion, therefore, mainly to what, after all, is our particular province—the problem of cancer as we see it in our work as medical men.

If one attempts to assess the position of the cancer problem to-day, one can thread one's way, without serious mishap or much discomfort, through a maze of statistics and figures. Some stages of that journey may be encouraging, others depressing, but one may emerge with a general feeling that more is being done for cancer than ever before; that the medical profession is more alive to the importance of early diagnosis; and that the public

TABLE I

	1912	1922	1932
Population	36,539,636	38,158,000	40,201,000
Deaths, all causes	M., 251,232 F., 236,707	247,221 239,559	245,715 238,414
Total	485,939	485,780	484,129
Deaths from cancer	M., 16,183 F., 21,135	21,256 25,637	28,829 31,857
Total	37,323	46,903	60,716
Deaths, breast cancer	M., 20 F., 3,736	42 4,525	47 6,385
Total	3,756	4,567	6,435

seeks advice earlier: facts which suggest that the problem is on the way to being solved. This conclusion is a comfortable one, and one for which there is at any rate some foundation, but it would be more justified if it were not for one or two important and very pertinent facts. Cancer is regarded with horror because it kills; so that the number of people who die from it, whether that number is increasing or decreasing, is some sort of touchstone by which we can judge of our efforts to deal with it.

* Given at Hull under the auspices of the British Empire Cancer Campaign.

I will recall two features, which have a bearing on the problem: first, the number of deaths from breast cancer in 1932 (Table I); and secondly, the figures showing the type of case presented to a general hospital for treatment (Table II). In the year 1932 there were 6,435 deaths from breast cancer, compared with 4,868 in 1922 and only 3,756 in 1912. Although the figures showing the type of case vary, the evidence is that cases presenting themselves at a time when there is a movable lump in the breast and no glandular involvement amount to less than 15 per cent. of the total.

These two facts in themselves are surely enough to justify further investigation, and I think it is not amiss to examine the Registrar-General's returns in greater detail. The total number of deaths from all causes has decreased slightly during the past twenty years; but if we consider the figure for cancer as a whole we find that there has been a marked increase. In the year 1932 there were 60,716 deaths from cancer. This represents a 30 per cent. increase on the figure given ten years previously, and an increase of over 60 per cent. on the figure for 1912. I have chosen breast cancer for the figure I first quoted because it may be argued that the increase in the reported deaths from the disease as a whole may be due to better methods of diagnosis, which reveal more cases of internal cancer. This consideration applies particularly to cancers affecting the alimentary tract and the respiratory system, but hardly affects the diagnosis of breast cancer, which, though it may be difficult in the early stages, becomes only too obvious as the disease progresses.

We are confronted, then, with the facts that deaths from cancer of the breast have increased alarmingly in the last twenty years, and that all too small a number of cases were presented for treatment at a stage when

TABLE II

	1922	1932
Digestive organs and peritoneum	M., 13,196 F., 12,348	17,703 15,435
Total	25,544	33,196
Respiratory organs	M., 1,430 F., 518	2,688 920
Total	1,948	3,608
Male genito-urinary	2,051	3,229
Skin	M., 515 F., 439	630 527
Total	954	1,157
Buccal cavity and pharynx	M., 2,685 F., 432	3,040 535
Total	3,117	3,575

there was a reasonable chance of cure. These things are true not only in breast cancer, but also in cancer of the buccal cavity, the digestive tract, the respiratory system, the male genito-urinary system, and the skin.

Having agreed that the problem is a difficult one and in more urgent need of solution now than ever before, how can we be constructive about it?

SURGERY AND RADIUM AND X-RAY THERAPY
REVIEWED

Our present methods of treatment are admittedly inadequate; let us first briefly review their results, and then inquire how far we are using them to the best advantage, and in what ways we can increase their efficacy. An accurate knowledge of the value of our present methods of treatment is not easily obtained in this country, owing to the difficulty of securing comparable statistics on a reasonably large scale. In November last, at the Royal Society of Medicine, Professor Gask stated that a general survey of figures led him to conclude that the best we can expect either from surgery or from radium is a five-year survival rate of 20 to 25 per cent. for tongue cancer, 35 to 40 per cent. for breast cancer, and 40 per cent. for uterine cancer. Hintze reported a five-year survival rate of 34 per cent. following the treatment of 5,500 cases of carcinomata of all kinds at the Surgical Clinic at Berlin. This group included 836 skin cases, in which the results of treatment are extremely good; without these skin cases the percentage would be considerably lower.

It is probable that surgery has reached the pinnacle of accomplishment, and that little more can be expected of surgical technique. Surgery will always be the method of choice in certain types of cancer, and indications for such operations are well known. In the case of radium and x-ray therapy the position is different. As a result of experience obtained over a period of thirty years, it is possible to assume that much more will be done by the use of these two methods of treatment, and that progress is slowly but surely being made. It must be urged at once that it is essential that surgery and radiation should not be divorced. They resemble each other in that their effects are local, and that they are used to combat a disease which frequently becomes general. During the past ten years a great deal of work has been done in relation to the physics, the action, and the dosage of radium, and although both over-enthusiasm and undue pessimism have characterized the development of radium therapy at times, advance has been steady even if it has been slow. The use of deep x-ray therapy has increased markedly in the last few years; better results have been due to improvement in technique, more accurate and standardized dosage, and the use of higher-voltage apparatus.

HOW TO USE THESE METHODS TO BEST ADVANTAGE

With these three main methods of treatment at our disposal it is essential that they be used in the right way, and that the results of such methods, either singly or in combination, should be carefully controlled. To get the most out of them certain things are essential.

First.—Every hospital at which cancer cases are treated should decide its own cancer policy. Members of the medical staff should agree as to the method of treatment to be adopted in various malignant growths.

Secondly.—Every cancer case should be followed up systematically by a department specially devoted to this purpose. The necessity of tracing the subsequent history of all cancer patients is too obvious to be stressed, but there are many hospitals where such a scheme would be impossible owing to the cost of the organization. In such case I suggest that the research activities of the particular hospital should be confined to one group of cases. Other groups would be treated, but the follow-up scheme would be limited to one disease. Everyone will agree that it is useless to treat cancer unless there are facilities for finding out the value of the methods adopted, and each hospital should have the necessary facilities.

Thirdly.—Records of cancer cases should be kept on a uniform basis. In order to obtain comparable cases from different hospitals notes should be as uniform as possible, and details should be given of special points in particular groups of cases. Forms such as those compiled by the National Radium Commission might be used with advantage for all cases of cancer, however treated. In this way mass statistics could be compiled; but it must be pointed out that statistics are valueless unless records are accurate and complete. By adhering to the common plan of note-taking a truer value of various methods would be obtained, and in addition much other useful information.

Fourthly.—Statistics must be compiled so that figures obtained in treatment by various methods are comparable. The difficulty of interpreting statistics which differ in form, however slightly, is well known. This is multiplied when dealing with the results of more than one method of treatment, so that the necessity of strictly comparable figures is essential.

Lastly.—There must be more co-operation between institutions and centres engaged in the treatment of cancer. In larger hospitals clinicians must be guided in their work by physicists and pathologists, and this is particularly important in carrying out radiological research. Co-operation must start in the individual hospitals, to be followed by co-operation in various counties and districts. Another point I would like to stress is the importance of a friendly liaison between the voluntary and the State hospitals. As a general rule the State hospitals receive a high percentage of advanced cases of cancer, many of which are beyond the help of even palliative relief. Finally, there should be some form of national pooling of results and methods, perhaps under the Ministry of Health or under the British Empire Cancer Campaign, which already controls the research activities of all those hospitals to which it extends a helping hand.

This need for co-operation has been much talked of lately; so much so that the word is apt to bring a smile to the lips of people who believe that it is a theory not easy to put into practice. I suppose there are few groups of men among the members of which co-operation is more difficult than among the members of the medical profession, who are, after all, engaged in a study which demands originality and independence of thought. It has even been whispered that they not only cannot get together, but they will not; this I, for one, refuse to believe. Nevertheless rapid progress will not be made until there is more liaison between workers in this field, and in view of the gravity of the problem it should be possible to secure co-operation by some or all the means I have suggested.

THE SIGNIFICANCE OF EARLY TREATMENT

Having attempted to outline the ways in which I think we can use to the best advantage the methods of treatment known to us, let us consider for a moment whether there is room for effort to increase the efficacy of such methods.

The significance of early diagnosis and treatment is too well known to need further emphasis. In fact, at the present time success depends directly on the stage of the disease at the time of treatment. I have little doubt that most of you will agree that early diagnosis is the most important single factor in the fight against malignant disease, and will remain so, even if other methods—serological or biochemical—are discovered which are capable of eradicating the disease when it is beyond the power of surgery and radiation. This is apt to be lost sight of by many, but if you were constantly confronted, as I am, with cancer cases in the advanced stage, where treatment starts with a severe handicap, you would be

left in little doubt as to its importance. Moreover, this importance is confirmed by actual figures—if not in all forms of cancer, then, at least, in some of the larger groups. For instance, the Ministry of Health reports on carcinoma of the breast—I refer to the valuable statistical work undertaken by Dr. Lane-Claypon and published in 1926 and 1928—show that when the growth is still local there is a five-year survival rate of 78.5 per cent., but when the axillary glands are involved this survival rate drops to 24.7 per cent.

Now it is reasonable to suppose that, although cancer becomes a general disease early, there is in most cases an initial stage at which the disease is entirely local. It is no less true that the failures of treatment are largely in those cases in which dissemination has already taken place, and that the best results are obtained when the disease is still local—that is, at the curable stage, curable because our present methods of treatment, whether surgical or radiological, are localized in their effects.

Figures published by the Ministry of Health show that when patients present themselves on account of carcinoma of the breast the average duration of symptoms has been nine months. This is confirmed by our figures at the Radium Institute. In a recent series the average duration of symptoms before treatment was 10.1 months in breast cases, 7.4 months in carcinoma of the cervix uteri, and 9.4 months in carcinoma of the rectum. Such figures seem to me to suggest that fear and ignorance play a most important part. The length of time is greater in breast cases than in the other two. In carcinoma of the rectum and cervix, "piles" and "the change of life" may easily confuse the issue.

The blame for delay, therefore, rests largely on the patient, who waits too long, either through sheer ignorance of what the signs and symptoms may mean, or because the patient suspects cancer and does not want to be told the truth. When we ask why the patient did not seek advice before how often does he reply that he thought it might be something serious? An illogical attitude, of course, but it must be remembered that cancer is still regarded by the public—and with some reason—as quite incurable. Doctors and nurses must be placed in this group. The frequency with which one sees advanced cases of cancer in medical men and women has often led me to doubt the value of educating the public, and in the educated sections of the lay public delay in seeking advice appears to be just as long as in the hospital class of patient.

EDUCATION OF THE PUBLIC TO SEEK EARLY ADVICE

Can the public be educated sufficiently to seek medical advice earlier? I think this should be possible, but it is important that a sense of proportion should be maintained. The widespread dissemination of warnings, in somewhat dramatic form, is certainly a grave danger, and is only likely to encourage cancerphobia. The publication of booklets, such as those prepared by the British Empire Cancer Campaign, is a step in the right direction, and should help a great deal. It seems to me, however, that despite a natural aversion to airing medical subjects in the lay press it should be possible to give advice without frightening people to death or offending the public taste. I am told on good authority that what is called the "news page" of the London daily newspapers is devoured greedily every day by hundreds of thousands of families. The advice given by the "Home Doctor" or "Our Medical Man" is treasured, and often cut out and preserved for future reference. Surely this is a medium which has been neglected. The daily press is, for better or for worse, the poor man's educator, and it seems illogical to ignore such a medium on the ground that information about cancer is likely to offend.

There are, of course, other ways in which the public interests might be served in this matter. Periodic free examinations might be offered to patients, and by this means a certain number of early cancers would be discovered. In the United States insurance companies give free examinations bi-annually to all life policy holders over 40. Such examinations are obviously in the interests both of the insured and of the company, and it would be a good thing if such a system could be instituted in other countries. This would apply to a large number of people, and would have the advantage of being a routine method connected with an important factor in the life of the individual—his life assurance; but this is a method open to very much the same objections as the routine bi-annual examination mentioned just now. A reliable serological test for malignant disease would be invaluable. It would probably be easier to persuade the public to have a periodic blood test than to submit to an extensive examination twice a year.

The heavy responsibility resting on the medical profession in the matter of early diagnosis is evident. The profession shoulders it very well indeed, but there is still room for improvement. If some of the apparently trivial signs and symptoms were investigated more frequently a larger number of cancer cases would be recognized in an early stage. This applies more particularly to growths of the alimentary canal, bladder, breast, uterus, lung, larynx, and hypopharynx. With our present methods of treatment a higher percentage of cures would certainly be obtained in the case of cancers of the breast, colon, uterus, and larynx. The practitioner must be constantly on the "look out" in order to recognize early symptoms of cancer, such as dyspepsia in a patient who has not previously suffered from indigestion, a husky voice, which may lead to the recognition of a laryngeal growth, and haematuria, which may be due to a bladder growth. Use should be made of all the accessory methods of diagnosis. For instance, all cases of haematuria, unless the cause is obvious, should be cystoscoped, and early resort should be had to radiological diagnosis of obscure but suggestive symptoms connected with the alimentary tract. No woman with post-menopausal bleeding should be allowed to go unexamined, and piles should never be diagnosed as the cause of rectal bleeding until after carcinoma has been excluded.

Although I have mentioned one or two ways in which the medical profession could improve its chances of getting early cases of cancer, I still believe that it is chiefly to the patient to whom we have to look for this. The patient does not help, largely because he is ignorant, and until his ignorance is removed, and he is at the same time convinced that he can be cured of his cancer if it is early enough; the greatest obstacle to progress will remain.

PALLIATIVE TREATMENT FOR ADVANCED CASES

To urge means whereby cancer cases may be treated at an early stage, and to visualize the time when patients will present themselves in a curable stage, does not absolve us from the responsibility of those patients who are beyond hope of cure. Such cases are lamentably numerous, and they do provide a serious part of the problem of cancer. The tendency is sometimes to decree that nothing can be done for the patient, and to feel that since no curative treatment is indicated that is the end of the case. It may be the end of the case, but it is by no means the end of the patient, who often has a long and arduous journey to take before he reaches the end. He is too often allowed to bear his burden alone, and without the help of many methods of treatment which we could use to alleviate his suffering. Many, and

perhaps the majority, of these patients are those in whom surgery has failed, and for whom further surgery is out of the question.

Radiation has a wide field of usefulness in many of these cases. I have not so far mentioned radium in connexion with the cancer problem because my subject is too general and my time too short to admit of consideration in any detail of special forms of treatment. As you will realize, however, it is difficult for me to consider radium and cancer as other than closely connected, and I make no apology for introducing the subject of radium therapy here, because its palliative use is perhaps its greatest contribution to the cancer problem. Inoperable cases of cancer of the mouth and fauces can, if care is taken, be treated so that foul ulcers heal and dysphagia is relieved, the patient dying from secondary deposits and being saved the miserable death which must otherwise be his lot. The offensive discharge and profuse bleeding in advanced cases of carcinoma of the cervix uteri can be stopped or diminished, and the patient's general condition is almost always improved. Fungating carcinoma of the breast can often be healed; the pain and foul discharge cease, and the patient dies a more comfortable death from secondary deposits at a later date. As a palliative measure in cases of carcinoma of the rectum radium is valuable, particularly in the lower ampullary growths; haemorrhage and discharge often cease, and the progress of the disease may become arrested for months, or even years, so that patients are kept comfortable, and colostomy is avoided in many cases. Enough work has been done on carcinoma of the bladder to say that many patients are given relief from pain and haemorrhage, sometimes for prolonged periods, by radium therapy.

X-ray therapy in expert hands is proving of more and more use in the palliative treatment of such conditions as pelvic tumours, bone sarcoma, and deep metastases affecting the spine and thorax. In addition to these methods, the general management of cases of incurable malignant disease is important. A great deal can be done by drugs, fresh air, and diet to make the end of the patient's life less intolerable than it would be in the absence of such measures.

RESEARCH AT THE RADIUM INSTITUTE

Whatever the direction of research in other spheres, clinical research is proceeding on definite lines, and is being justified even now by results. I refer to research in radiation therapy, both deep x-ray and radium therapy, and I believe that in another ten years these methods will have gone far to solve this problem for us, even in the absence of some startling biochemical or serological discovery which would revolutionize our conception of cancer treatment.

While radium and deep x rays have established themselves as the treatment of choice in certain malignant diseases, developments are taking place with regard to therapy by telerradium and by the use of x rays of increasingly higher voltages. Radium beam therapy, employing from 3 to 5 grams of radium, has already given encouraging results in other countries. There is no doubt that the work done by this mass irradiation has given, in certain cases, results which are not attainable by any other method of treatment. It appears to be the most effective of all forms of radium therapy, and is not associated with any special danger either to the patient or to the workers.

Due to the initiative of Professor J. C. McLennan a radium unit of the Stockholm pattern has been installed at the Radium Institute under the control of a governing body. The Union Minière de Haut Katanga has generously lent 5 grams of radium element for this research,

and later, if necessary, will increase the quantity to 10 grams. Most of the cases treated have been growths of the upper air passages, and the method has already shown signs of great promise. Recently a gift of £5,000 for purposes of cancer research was made to the Radium Institute, working in co-operation with another hospital. Part of this money is being used to set up a plant at the Mount Vernon Hospital capable of supplying very high voltage x rays. This research will also be directed by the committee which controls the radium beam unit. These parallel experiments are being carried out scientifically and on a large scale under the direction of the committee, and are an illustration of the importance of such co-operation in the treatment of cancer.

In this type of research particularly there must be frank exchange of ideas, so that experience can be pooled. I would like to see a number of centres established throughout the country devoted to deep x-ray and the radium beam treatment. Each centre would have a definite policy, which should be known to the other centres in order to prevent overlapping. To carry out such a research it must be on a large scale, and a sufficient number of cases of the type required should be available. It is here that help from medical men outside the centre is so essential. Every effort should be made to supply the units with the type of case required, and later to assist in following up the patients. Not only is this necessary in the interests of patients, but without such co-operation it is impossible for the centre to achieve good results. It is only by organized research that we can attempt to standardize methods of treatment.

There are many other aspects of this great problem which deserve attention, but my time is ended, and there remains only to define briefly the present position. Despite our gradual progress towards the goal, variously defined as the discovery of the cure or of the cause of cancer, it is still impossible to tell how near that goal is, or how long it will be before we reach it. When it is reached it may be that all our present methods will be proved wrong, and that they will have to be discarded. One often hears it said that those methods are obviously wrong, mainly because they are local weapons against a general disease. Nevertheless, they are the best we have, and the goal being an unknown distance away we must meanwhile make every effort to use them as efficiently as possible. The problem of cancer treatment is the problem of getting the most out of unsatisfactory methods, and I have attempted in this short lecture to tell you what, in my opinion, are the ways in which improvements could be made. Early diagnosis, in which the patient's help can and should be secured, and close co-operation, which is a matter for the medical profession, are certainly possible. There are obstacles in the way of both these things, but I feel as certain that those obstacles are not insuperable as I am that advance will be held up while they are allowed to remain.

The annual meeting of the University of London Medical Graduates Society was held at the Langham Hotel on May 8th, when reference was made to the fact that this society contains within its membership all three of the medical peers—Lord Dawson, Lord Moynihan, and Lord Horder—and also Dr. Helen Mackay, the first medical woman to be elected to the Fellowship of the Royal College of Physicians of London. Mr. W. McAdam Eccles was elected president of the society, Sir Charlton Briscoe honorary treasurer, and Mr. W. E. Tanner joint honorary secretary. At the dinner which followed, Sir Henry Brackenbury was the guest of the evening, and the president paid tribute to him as an outstanding member of the profession, as general practitioner, member of the General Medical Council, and Chairman of Council of the British Medical Association. The retiring president, Lady Barrett, replied to the toast of "The Society."

COMPARATIVE ASPECTS OF LOUPING-ILL IN SHEEP AND POLIOMYELITIS OF MAN*

BY

W. S. GORDON

ANIMAL DISEASES RESEARCH ASSOCIATION, MOREDCUN INSTITUTE,
GILBERTON, MIDLOTHIAN

By louping-ill in sheep is currently understood a disease characterized by cerebellar ataxia and disorder of brain and spinal cord functions, lasting about a day in acute infections to some weeks in chronic cases. In the latter type paralysis of one or more limbs is generally present. The mortality in definite clinical cases is high, but animals which recover do not usually develop another attack. The association of the disease with particular pastures is well established, and a large proportion of sheep brought from a locality in which louping-ill does not occur into a louping-ill district are liable to develop the disease.

The first conclusive contribution on the causation of this disease was made by Pool, Brownlee, and Wilson¹ in 1930, and the earlier literature on louping-ill has already been reviewed by Pool.^{2,3} These authors recorded the successful transmission of louping-ill in series from sheep to sheep by intracerebral inoculation with material obtained from the central nervous system of affected animals. The pig was also shown to be susceptible.

FEATURES OF LOUPING-ILL

In continuation of the work of Pool, Brownlee, and Wilson, investigations^{4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22,23,24,25,26,27,28,29,30,31,32,33,34,35,36,37,38,39,40,41,42,43,44,45,46,47,48,49,50,51,52,53,54,55,56,57,58,59,60,61,62,63,64,65,66,67,68,69,70,71,72,73,74,75,76,77,78,79,80,81,82,83,84,85,86,87,88,89,90,91,92,93,94,95,96,97,98,99,100} at the laboratories of the Animal Diseases Research Association established that:

1. The infective agent is a filterable virus which is communicable to mice as well as to sheep.
2. The pathological changes in the disease are essentially those of an encephalomyelitis.
3. The virus may be present in an infected sheep without producing typical louping-ill, but blood drawn at an early stage of the febrile reaction, which is a prodromal symptom of this infection, contains the virus.
4. Atypical manifestations may comprise merely a febrile reaction, or the sheep may die without lesions in the brain and spinal cord.
5. Under natural conditions louping-ill is tick-borne, the vector being *Ixodes ricinus* L., which is habitually present on louping-ill pastures.
6. Recovery from infection, either naturally or experimentally produced, results in immunity.
7. The investigation of louping-ill has revealed the presence of another tick-borne infection of sheep. This disease, which has been named "tick-borne fever," is clinically, pathologically, immunologically, and aetiologically distinguishable from louping-ill, but it probably aggravates the harmful effects of the latter.

That the causal organism of louping-ill is a filterable virus is now generally accepted (Alston and Gibson,¹⁶ and Czarkowska-Gladney and Hurst¹⁷). Hurst¹⁷ infected monkeys, and Findlay and Elton¹³ transmitted the disease to field voles. We possess unpublished evidence that cattle are also susceptible, and may develop the disease naturally. Rivers and Schwentker¹⁴ record that human beings who have come into close contact with the virus of louping-ill may develop in their serum neutralizing antibodies against the active agent, and illness suggestive of louping-ill infection is reported in three such individuals.

Our investigations into the pathogenesis of the disease in sheep and methods of prevention will soon be published in detail, but it may be stated here that there is a prodromal period in the naturally occurring disease, characterized by a diphasic fever. Virus can invariably be detected in the blood during the early part of the first febrile phase. The second febrile phase usually marks the commencement of symptoms indicative of invasion of the central nervous system, and then virus is generally absent from the blood. Many natural cases of louping-ill, however, are abortive. In some of these symptoms of central nervous system infection appear and pass off, whilst in others the only indication is dullness accompanying the characteristic febrile reaction. Abortive attacks can be diagnosed definitely by detection of virus in the blood during the first febrile phase. This diagnosis is made by intracerebral inoculation of mice with citrated blood. There is also evidence that subcutaneous inoculation with formalinized vaccine, prepared from the brain and spinal cord of infected sheep, produces antibodies capable of neutralizing virus introduced into the general circulation, thus preventing the active agent from invading the brain and spinal cord. This vaccine does not immunize the central nervous system, but extensive field trials show that it affords a considerable degree of protection against the natural infection. These observations suggest that the primary multiplication of this so-called neurotropic virus occurs outside the brain and spinal cord.

COMPARISON WITH POLIOMYELITIS

Since this is a discussion in comparative medicine, it seems appropriate to direct attention to the somewhat similar syndrome of naturally occurring louping-ill in sheep and the course of poliomyelitis infection in man. Of course it is not suggested that the two diseases are identical, but, since the pathogenesis and epidemiology of poliomyelitis are subjects of considerable controversy, the study of louping-ill in sheep may present some noteworthy features to those interested in poliomyelitis. At the outset I would mention that, having no personal knowledge of poliomyelitis, I am greatly indebted to the Report by the International Committee on Poliomyelitis,¹³ organized by Jeremiah Millbank of New York City.

The medical pathologist, whose material is man, is drastically handicapped by the limited extent to which experiment on the natural material is open to him. He must take his problems as he finds them, and deny himself the help of almost all the preliminary simplifications which are the essence of the veterinary pathologist's advantage. When one's patient can be used as one's experimental animal, circuitous methods of investigation in determining the pathogenesis of a disease do not require to be adopted. Thus the investigation of louping-ill has been greatly facilitated by the fact that sheep, which are naturally susceptible to the disease, are also suitable experimental animals. Such facilities permit a study of the propagation of the infective agent in its natural host, and enable one to place greater reliance on the conclusions drawn regarding the natural route of infection and the epizootiology of the disease than can be placed on similar studies with an infective agent which has been adapted by artificial methods to an experimental animal. In the case of louping-ill the mouse is a susceptible experimental animal, which we have used mainly for detecting the presence or absence of virus in a given tissue. Fortunately, sheep have been available in which to study the pathogenesis of the disease. It has not been necessary to make these studies on the mouse and to argue from the analogous disease in that animal as to the nature of the infection in sheep.

* Opening paper in a discussion in the Section of Comparative Medicine, Royal Society of Medicine, November 22nd, 1933. Published by permission of the Society (*Proc. Roy. Soc. Med.*, 1934, vol. XXVII, Sect. Comparative Medicine, p. III).

AETIOLOGY AND SYMPTOMATOLOGY

Each disease is caused by a filterable virus which possesses neurotropic characters. Schwentker, Rivers, and Finkelstein¹⁶ showed that immunologically louping-ill and poliomyelitis are not closely related. Incidentally, it might be noted that the poliomyelitis virus used in their experiments was the "mixed strain" virus highly adapted to the monkey. Now it appears from the work of Burnet and Macnamara,¹⁷ Weyer,¹⁸ and others, that repeated passage of poliomyelitis virus through monkeys causes it to change immunologically, and the recent work of Paul and Trask¹⁹ shows that there is a qualitative immunological difference between a freshly isolated strain from a human source and a monkey-adapted strain. Accordingly, the question of immunological relationship between louping-ill virus and a freshly isolated "human" strain of poliomyelitis virus still remains open. The incubation period of naturally occurring louping-ill is rarely less than six, or more than eighteen, days from the time of infection until the appearance of clinical symptoms. This corresponds with the incubation period of poliomyelitis infection. In the prodromal period of louping-ill infection there is usually a diphasic temperature reaction, and the second febrile phase is accompanied by the appearance of the first symptoms of nervous derangement, if these develop. This corresponds with the so-called "dromedary" type of prodromal symptom described by Draper²⁰ for poliomyelitis.

Virus in the Blood

The virus of louping-ill has been detected in the blood of infected sheep concurrently with the initial rise in temperature, and in most instances a fall in temperature is followed by the disappearance of much or all virus from the blood. The virus of poliomyelitis has not been detected in human blood, but I am not aware of systematic daily examination of blood having been made during the prodromal stage. Arguing from the analogy of louping-ill, it is highly improbable that virus would be present in the blood when the symptoms of paralysis had developed. Flexner and Lewis²¹ were able to show the presence of virus in monkey's blood if large quantities were drawn at the height of the disease. If the monkeys showed symptoms of nervous system involvement at the time the blood was taken these workers were probably fortunate in detecting virus. Leiner and von Wiesner²² also reported success in one out of five tests with blood drawn from monkeys at different stages of the disease. Clark, Fraser, and Amoss²³ were successful in finding virus in the blood of monkeys in one out of ten instances; the important point about this positive result, however, is the fact that blood was removed at a fairly early stage of infection—namely, at the beginning of paralysis on the seventh day following intracerebral inoculation.

In poliomyelitis it may yet be found that, as in louping-ill, virus is invariably present in the blood during the early stage of the febrile reaction, and generally absent from the blood when paralysis has developed. In clinically obvious cases of poliomyelitis paralysis of one or more limbs usually occurs. During epidemics the so-called abortive (Wickman type) and non-paralytic types of the disease have been recorded. The most convincing evidence of the occurrence of abortive cases has been furnished by Paul and Trask,²⁴ who isolated poliomyelitis virus from the throats of two patients during a characteristic minor illness which was not followed by paralysis.

In chronic cases of louping-ill, paralysis of one or more limbs usually develops, and on farms where the disease is prevalent sheep with various types of deformity are

usually encountered. As already stated, the existence of abortive cases of louping-ill has been definitely established by the detection of virus in the blood during a febrile reaction, which was the only clinical manifestation of infection other than dullness and loss of condition; such atypical infections are followed by immunity.

RESISTANCE AND IMMUNITY

It is stated that the low case incidence of epidemic poliomyelitis has generally been taken to indicate that many persons are exposed to the virus without developing the typical paralytic disease. This inference, however, is only an indirect one, and not based on any direct experimental evidence. The analogous evidence in the case of louping-ill is direct, since the specific virus has been detected in the blood of sheep during a minor illness accompanied by a febrile reaction which was not followed by paralysis. Further, in one of our experiments, forty-nine susceptible sheep were exposed to the risk of natural infection for two months: 53 per cent. of the animals died from all causes, and 60.9 per cent. of the survivors had acquired immunity to louping-ill.

As in poliomyelitis one attack of louping-ill usually confers immunity, and in both diseases neutralizing substances develop in the blood of infected individuals. The only reliable method of producing a typical case of louping-ill in sheep is by introducing the virus directly into the central nervous system. Subcutaneous or intravenous inoculation with virus is often followed by an abortive attack, or only a febrile reaction. In some instances, however, the typical disease, with involvement of the central nervous system, is produced. Intranasal insufflation with virus is an unreliable method of producing infection; admittedly, infection can be produced by this route, but if it occurs under natural circumstances it must be very rare. We have now had over 2,000 sheep under experiment without observing any precautions to prevent spread by contact, and we have no evidence to suggest that infection may spread by this means. The evidence on this point in regard to poliomyelitis in man is rather conflicting.

Active Immunity by Vaccine

In considering methods of prophylactic vaccination for the control of louping-ill it was found that the central nervous system is a difficult tissue to immunize. Thus formalinized vaccine inoculated subcutaneously does not protect sheep from virus injected into the brain, whereas it does protect against virus introduced subcutaneously. Subcutaneous injection of living virus, when followed by a febrile reaction in the inoculated animal, produces immunity of the central nervous system, but this method of immunization is attended with the risk of setting up the disease. Since, under natural circumstances, the disease is transmitted by a blood-sucking arachnid, and the primary multiplication of virus occurs in the blood, it was considered that the immunity afforded by the formalinized vaccine might be sufficient to prevent the natural infection. As already stated, although this vaccine does not produce immunity of the central nervous system, it is proving to be efficacious in the control of the natural disease.

Monkeys can be immunized against poliomyelitis by the subcutaneous inoculation of living virus. As in louping-ill the method is attended by the danger of setting up the disease. To quote one example, Leiner and von Wiesner²² inoculated four monkeys; one died of typical poliomyelitis after four injections, one developed the marantic type of the disease, and two died of an intercurrent infection. Success has not attended the efforts to produce immunity by means of dead virus

vaccines. From the analogy of louping-ill this is not surprising, since the immunized animals were tested by intracerebral inoculation.

PATHOLOGY

The essential pathological changes in the two diseases are closely similar, and are mainly confined to the central nervous system, where inflammatory changes occur with destruction of nerve cells, mainly the anterior horn cells of the cord in poliomyelitis, and the Purkinje cells of the cerebellum in louping-ill. From the comparative point of view it is essential to draw attention to the fact that, although the sheep, mouse, and pig are all susceptible to louping-ill, the nature of the reaction in the central nervous system of these animals varies. Thus in the case of the sheep, as the lesions suggest, cerebellar ataxia is the main symptom. In the mouse the nerve cells of the cord are mainly affected, and paralysis of one or more limbs usually occurs; whilst in the pig, which generally does not develop a fatal disease, the interstitial reaction predominates. Even in animals of the same species variation in the extent and location of lesions in the central nervous system may occur, with consequent deviation in the symptoms from those generally accepted as typical.

EPIZOOTIOLOGY

In forming an opinion on the epizootiology of louping-ill it is probably well to bear in mind the insulatory mechanism which guards the central nervous system from injurious substances of haematogenous origin. Wilfred Trotter²³ gives a very clear conception of this mechanism. After reviewing evidence, he states:

"We have a group of well-defined facts established by countless observations and capable of confirmation any time. They bring evidence from different parts of the nervous system, disclosing, even to superficial consideration, a clear, common tendency. The conclusion to which all point is that breaches of normal coverings of the nervous tissues, allowing contact between the latter and other tissues of the body, result of necessity in energetic local reactions. The obvious function of such reactive processes is to re-establish the normal discontinuity between neural and somatic tissues, and to break the contact that has caused the disturbance."

McIntosh and Fildes²⁴ showed that after intravenous injection of salvarsan and neosalvarsan in man and animals no arsenic could be found in the brain, although its presence could be detected in tissues outside the central nervous system. This phenomenon is not due to a lack of affinity between the brain and the drugs, but to an inability on the part of the drugs to penetrate into the substance of the brain.

After subcutaneous inoculation of massive doses of potent antitoxin in sheep we have found that although the antitoxin can be detected in the blood its presence cannot be detected in the cerebro-spinal fluid. Whilst it cannot be argued that these substances are comparable to a living virus, the evidence suggests that injurious materials present in the blood have very definite barriers to overcome in gaining access to the central nervous system. It would appear that the epizootiology of louping-ill is closely linked with this fact, and the perpetuation of the disease in enzootic form is dependent on a high case incidence of the so-called abortive form, with a relatively low incidence of clinical cases—that is, cases in which virus has invaded the central nervous system.

This aspect of the problem may also have some bearing on the explanation of the epizootiology and epidemiology of other diseases caused by so-called neurotropic viruses. It is a practical observation that a large proportion of

the old sheep on a "diseased" farm possess immunity to louping-ill, although they have no history of a clinical attack of the disease. Even in a group of yearling sheep received from diseased farms, Pool, Brownlee, and Wilson found that 20 per cent. were immune, and in our own experiments it was found that after exposure of susceptible sheep to the risk of natural infection for two months as many as 60.9 per cent. of the survivors had acquired immunity.

Endemic poliomyelitis occurs in its greatest incidence in children up to 5 years of age. It has an inexplicable seasonal incidence, and is generally regarded as a summer disease. Enzootic louping-ill is generally confined to lambs and yearling sheep; it also has a seasonal incidence, occurring in the spring, and, to a lesser extent, in the autumn. The seasonal incidence of louping-ill corresponds with the season of maximum activity of ticks, which are the vectors of the disease. When an epizootic of louping-ill occurs in a sheep stock in which the disease has not been previously recognized, animals of all ages are liable to become affected. Similarly, epidemics of poliomyelitis in virgin soil have the same tendency. In the International Committee's Report three virgin soil outbreaks are described—one upon the island of Guam in 1899, reported by Grunwell; one upon the island of Nauru in 1910, reported by Müller, and one in New Guinea in 1929, reported by Maenamara. Each outbreak was characterized by a high mortality, mainly confined to young adults. An extraordinary feature common to each outbreak was the apparent immunity enjoyed by the children. This is a peculiar phenomenon, and might suggest that the incidence of subclinical cases in children is greatly in excess of frank cases, with definite involvement of the central nervous system, whereas the same may not apply to non-immune young adults.

Among the many opinions on the epidemiology of poliomyelitis the one expressed by Lavinder, Freeman, and Frost²⁵ is of particular interest. They state that

"while the incidence among a population affected by poliomyelitis even in its severest epidemic form is usually not high, yet this disease possesses not infrequently the power to spread widely—in fact, to become pandemic in a country. It has been suggested that an epidemic of infectious disease may be viewed as the resultant of two excursions, a vertical one representing the heaping-up of cases in any locality, as usually shown plotted on a chart, and a lateral one, representing the extent of territory covered—the geographic distribution. Epidemic diseases not infrequently show decided variation in these two movements. Certain of them, like dengue, for example, show a most striking vertical movement along with a very limited lateral movement. Poliomyelitis has exhibited a significant power of lateral movement, and, up to the present time, in much greater degree than its power of vertical excursion."

This "creeping tendency," as Dale²⁶ calls it, is suggestive of a limiting factor of host resistance, a sparse but widely spread population at risk, and a widespread virus. This opinion on the epidemiology is compatible with the view that poliomyelitis may be a systemic infection with the specific virus which, under favourable conditions, successfully invades the central nervous system, and is responsible for the symptom-complex of poliomyelitis. Such a definite view would materially assist in solving many of the baffling problems in the epidemiology of poliomyelitis.

In view of the modern trend of opinion (Walsh, Annual Meeting of the British Medical Association, 1933) that poliomyelitis is probably from the outset and exclusively an infection of the nervous system, it may be of comparative interest to draw attention to the fact that in an analogous disease of sheep—namely, louping-

ill—there is a high infection incidence of the young population, a large proportion of the cases being sub-clinical infections which can only be diagnosed by detection of virus in the blood, and a small proportion of frank cases with symptoms indicative of central nervous system infection. Thus, in the perpetuation and spread of this disease systemic infections probably have a more important role than actual clinical cases.

SUMMARY

Louping-ill, an encephalomyelitis of sheep, is caused by a filterable virus possessing neurotropic characters. Under natural conditions of infection the disease is tick-borne, the vector being *Ixodes ricinus* L. At first it would seem a curious anomaly that a blood-sucking arachnid has the role of transmitting a neurotropic virus, but the apparent anomaly is explained by the fact that multiplication of this so-called neurotropic virus occurs primarily in the blood. Invasion of the central nervous system by the virus occurs at a late stage in the infection, and is responsible for the characteristic symptoms of the disease. In the naturally occurring disease, invasion of the central nervous system is not a constant feature. Cases occur in which virus does not gain access to the central nervous system. Such abortive types of the disease can be diagnosed by the detection of virus in blood drawn at an early stage of the febrile reaction which accompanies the infection. It seems highly probable that the incidence of abortive types of the disease is greatly in excess of the number of frank cases with central nervous system involvement.

From a comparative point of view the study of louping-ill in sheep would suggest the possibility that in the early stage of poliomyelitis in man, before obvious clinical symptoms have developed, the specific virus may be present in the blood. If such early blood infection were demonstrated present views regarding the nature of poliomyelitis infection, its prevention, and treatment would require revision.

URINARY EXCRETION OF OESTRIN ADMINISTERED UNDER EXPERIMENTAL CONDITIONS AND AFTER THE MENOPAUSE

BY

J. M. ROBSON, M.D., B.Sc.

(Beit Memorial Research Fellow)

T. N. MacGREGOR, M.B., Ch.B., F.R.C.S.Ed.

R. E. ILLINGWORTH, B.Sc., Ph.D.

AND

N. STEERE, M.B., Ch.B.

(From the Institute of Animal Genetics, University of Edinburgh, and Dr. James Young's Gynaecological Clinic, Royal Infirmary, Edinburgh)

That oestrin is excreted by the human female in the urine and faeces at various stages during active sexual life is now definitely established. The quantities excreted show regular alterations during the menstrual cycle, these variations applying to the amounts found in both the urine and the faeces, and being greatly increased during pregnancy. A less marked increase in the oestrin excretion is also noted during the early stages of the menopause. The fluctuations in the elimination of oestrin correspond in general to changes in the hormone content of the blood. When, however, we come to consider the question as to how much oestrin is actually produced in the body at these different stages, and whether the hormone produced is quantitatively excreted without undergoing any changes, there are few experimental data on which any conclusions can be based. A similar paucity of information exists with regard to the function of the renal and intestinal barriers, and the problem of whether these play any part in determining the excretion of the sex hormone.

Zondek (1931) has, indeed, reported one case in which the elimination of oestrin was studied. The patient was oophorectomized for ovarian tumour, and subsequently the parenteral administration of 10,000 mouse units of oestrin was followed by excretion of 60 per cent. of the hormone in the urine within thirty-six hours. As some of the hormone was presumably also excreted in the faeces, the figures suggest that only a small percentage of the oestrin introduced in the body was retained and not excreted. On the other hand, both Siebke (1930) and Siebke and Schuschania (1930) also investigated the hormone excretion in the urine and faeces following the repeated administration of known doses both parenterally and hypodermically, and concluded that a large proportion of the hormone is not excreted, and must therefore, in some way, be used up or metabolized in the body.

OBJECT OF INVESTIGATION

Now knowledge as to the fate of the oestrous hormone is important for a number of reasons—namely:

1. It may help us to understand more perfectly the nature of the sex cycle and its relation to hormonal activity.
2. It will allow of a more exact interpretation of the diagnostic significance of data on the presence of the hormone in the excretions—in relation to the hormone production and activity.
3. It may help in the evaluation of the doses necessary to bring about certain desired therapeutic effects.
4. In view of the great variety of active oestrous-producing compounds now isolated, it may afford information as to which of these may be the most suitable in relation to the normal metabolic processes.

It was therefore decided to attempt to determine the fate of known quantities of a definite form of oestrin administered under strict experimental conditions. For the preliminary experiments it was deemed advisable to use subjects in which the normal oestrin production had presumably already ceased; and for this reason the experiments were all performed on patients in whom both ovaries had been surgically removed, or in whom the onset of the menopause had led to a cessation of the normal ovarian activity.

TECHNIQUE

The preparation used in these experiments was ketohydroxy-oestrin (obtained from B.D.H.). Samples were standardized by injecting four doses in oil over thirty-six hours into ovariectomized mice, and showed by this method a potency of about 5,000 mouse units per mg. The hormone was dissolved in absolute alcohol (1 mg. per c.cm.), and immediately previous to injection was diluted with four parts of water. Injections were in all cases given intramuscularly. The urine was collected for definite periods before and after injection. In the first experiment it was injected without treatment into the mice; this, however, proved rather toxic, and did not allow of a satisfactory estimation of the oestrin content.

RESULTS

As it was expected that the injection of the large doses of oestrin would be followed by the excretion of at least a substantial part of it, it appeared likely that standardization would be possible by means of the injection of the untreated urine. This expectation was not, however, realized. The procedure was adopted in the first case given in the table, but the whole of the urine passed during the first twelve hours following the injection contained less than 145 mouse units of the hormone (when standardization was performed by administration of four doses over thirty-six hours). Smaller amounts could not be detected, as the urine proved toxic when injected in the larger doses. Thus in this case, of the 5,000 mouse units of oestrin injected, less than 145 mouse units were excreted in the urine during the first twelve hours immediately following the administration.

In the next two cases the urine was not itself injected but extracted with ether, as described above under the heading "Technique." In both cases the ovaries had been previously removed, so that there could presumably be no question of any oestrin production by the patients.

Case No.	Age	Condition	Oestrin Content of Urine in 12 Hours Pre-injection Period	Amount of Oestrin Injected	Amount of Oestrin in Urine Following Injection									Blood Assay	
					First 12 hours	Second 12 hrs.	Third 12 hrs.	Fourth 12 hrs.	Fifth 12 hrs.	Sixth 12 hrs.	Seventh 12 hrs.	Eighth 12 hrs.	Material Assayed	Time After Oestrin Injection	Oestrin Content M.U. per Litre
I	57	Post-menopausal (15 years)	—	mg. 1.0	M.U. <145	M.U. <140							Urine		
II	46	Bilateral ovariectomy	—	1.0	<33	24-72	>15						Ether extract of urine		
III	39	Bilateral ovariectomy	—	2.0	65	24-95						<10	Ether extract of urine		
IV	54	Post-menopausal (10 years)	5-10	2.0	500-1,250	100-350				<20			Ether extract of hydrolysed urine	1½ hrs.	<25
V	52	Post-menopausal (4-5 years)	>10	2.0	100				50				Ether extract of hydrolysed urine	4 hrs.	<25
					<33								Ether extract of urine		
VI	51	Post-menopausal (7 years)	<9	2.0	10-100		<60						Ether extract of hydrolysed urine		

In later experiments the oestrin was therefore extracted by the following methods:

1 Portions of 270 c.cm. urine were acidified by the addition of 30 c.cm. 10 per cent. H_2SO_4 and extracted with ether continuously for not less than eight hours in a continuous extractor. The ether extract was evaporated to dryness, and the residue dehydrated by several evaporations from solution in absolute alcohol. The dry residue was then dissolved in a mixture of ether and alcohol, and the requisite amount of maize oil added. The volatile solvents were removed by gentle heat, and the urine extract in the oily medium standardized.

2 In most instances the urine was boiled in acid solution for a number of hours before extraction with ether. Portions of 270 c.cm. urine were acidified with H_2SO_4 , as above, and the urine subjected to boiling under a reflux condenser for periods of about eight to twelve hours. The hydrolysate was then transferred to the continuous extraction apparatus and extracted with ether. The ether extract was treated as already described. Blood was also collected in two cases. The treatment of the blood samples was similar in every respect to the second process, described above for urine, except that the residue obtained on evaporation of the ether extract was dissolved in absolute alcohol and administered to the test animals in that form.

In all cases standardization was performed by the injection of four doses over thirty-six hours, the unit being taken as that amount which would produce cornification in 50 per cent of the animals. In some cases, instead of attempting to obtain an exact figure, the amount of oestrin present in the sample was only determined within certain limits (see Table).

In the first of these cases 5,000 mouse units of oestrin (1 mg.) were given, and the second case received twice that amount. The amounts of oestrin excreted are shown in the table. It was found that the excretion of the hormone appeared again very small. Thus in Case III, which received about 10,000 mouse units (2 mg.), the extract made from the total urine collected during the twelve hours following the injection contained only about 65 mouse units of oestrin, while during the next twelve hours the urine contained (as determined by ether extraction) more than 24 mouse units and less than 96 mouse units (probably about 50 mouse units). Four days after the injection no more oestrin was detectable in the urine by this method.

The very small amounts of oestrin found in the urine in these two cases raised doubts as to whether all the hormone was being excreted in a form which could be extracted by ether. Dr. Marrian, from whom we inquired in regard to this question, kindly informed us that oestrin may be excreted in a form (probably a sulphate-ester) which is insoluble in ether, but which becomes soluble after hydrolysis. We thereupon performed the following experiment:

Two hundred and seventy c.cm. of urine obtained from a pregnant woman was extracted with ether for several hours. This ether extract was then dissolved in oil and standardized in the usual way, and was shown to contain definitely less than 120 mouse units of oestrin per litre of urine. The extracted urine was then hydrolysed for several hours with

H₂SO₄ and again extracted with ether. This extract was dissolved in oil and standardized. It contained more than 120 mouse units per litre but less than 600 mouse units per litre, the results showing that the actual amount was nearer the latter figure.

Hence, of the total amount of oestrin in this sample of urine only a small proportion (probably less than a quarter) was extractable by ether, the remainder becoming so only after hydrolysis.

In the next three cases, therefore, the urine was hydrolysed before extraction with ether. The excretion was, as in the previous cases, determined at various stages after injection, the dose administered being in all cases 2 mg. of oestrin—that is, about 10,000 mouse units. It will be noticed in the table that by this method the figures obtained are rather larger; yet only in one of these cases (Case IV) was the amount excreted at all large; for in the first twelve hours after the injection the urine contained about 1,000 mouse units of oestrin, but in the following twelve-hour period the urine contained a much smaller quantity of the hormone (more than 100 and less than 350 mouse units). By the third day after the injection the oestrin administered appeared to have been completely eliminated, as the urine contained only small amounts of the hormone. In the other two cases the proportion of injected oestrin which was excreted in the urine was even smaller, the total amount in the twelve hours following the injection being less than 100 mouse units.

In one of these cases (Case V) the proportions of oestrin excreted in ether-soluble and insoluble forms were investigated. A portion of the urine excreted during the first twelve hours following the injection was extracted with ether (without previous hydrolysis) and the extract standardized. It contained definitely less than 30 mouse units of oestrin per litre of the original urine. Another portion of the urine was first hydrolysed for several hours and then extracted with ether. This extract contained about 100 mouse units of oestrin per litre of the original urine. The residue of this extraction was further hydrolysed for a number of hours, and then again extracted with ether, but no oestrin could be detected in this extract. Hence, according to this experiment, less than one-third of the oestrin excreted in the urine was in an ether-soluble form (though the original material injected is ether-soluble).

Another interesting fact which emerged in the course of this investigation was that oestrin may be excreted in the urine several years after the onset of the menopause and cessation of menstruation, and in quantities apparently substantially similar to those present in the urine during the normal menstrual cycle. This was observed in two out of the three cases investigated. In Case V, a patient 52 years old, and investigated four to five years after the complete cessation of menstruation, the twelve-hourly sample collected before the injection of oestrin contained more than 10 mouse units of oestrin, corresponding to an excretion of the hormone of more than 20 mouse units per day. In Case IV, aged 54, and investigated ten years after the menopause, the excretion was about 10 to 20 mouse units per day. On the other hand, no appreciable amount of oestrin was detected in the urine of Case VI, aged 51, and investigated seven years after the menopause. In all these cases the urine was hydrolysed before extraction with ether.

An attempt was also made to detect oestrin in the blood after the administration, but in both cases investigated the extract obtained from 40 c.cm. of hydrolysed blood contained less than 1 mouse unit of the hormone. In the first case the blood was collected eleven and a half hours after the intramuscular injection of the hormone,

and this long interval might account for the small amounts of oestrin in the blood; but no such explanation can be offered in Case V, where the blood sample was taken four hours after administration of the oestrin.

DISCUSSION

The experiments reported clearly demonstrate that when ketohydroxyoestrin is injected into the human female subject only a small proportion of the hormone can be recovered in an active form from the urine by the methods used, which included not only thorough extractions with ether, but a similar extraction following prolonged hydrolysis. Moreover, the result is confirmed by the one experiment in which the urine was injected into ovariectomized mice without any previous treatment; for, although the toxicity of the urine rendered an accurate assay impossible, yet it could be definitely established that the quantities were comparatively small.

In view of the results of Siebke and Schuschania (1930), it is likely that some of the hormone was also excreted in the faeces, but, even allowing for this, only a portion of the amount injected can be accounted for. The proportion of the hormone excreted was not the same in all the subjects investigated. Assuming that the amount eliminated in the faeces is similar to that found in the urine, then the total amount of oestrin recoverable might, in Case IV, be equal to nearly one-quarter to one-third of the dose injected. In the other cases, however, and on a similar basis, it can be computed that less than one-twentieth of the hormone injected appears in the excreta. These results are, generally speaking, in agreement with those reported by Siebke (1930) and by Frank, Goldberger, and Spielman (1932) in the menstruating woman. They show, moreover, that even after cessation of menstruation—after the menopause or after the removal of the ovaries—the conditions are still substantially the same.

In view of these results it is difficult to escape from the conclusion that the human body can rapidly destroy, or at any rate render inactive, the oestrous hormone, and this view is supported by the finding that, four hours after the injection of 10,000 mouse units, the blood contained less than 25 mouse units of the hormone per litre (Case V). It may be mentioned that the evidence obtained by Fee, Marrian, and Parkes (1929) on the isolated heart-lung preparation also suggested that oestrin could be rapidly destroyed.

Further, the finding that a large amount of the hormone which appears in the urine is in a form not extractable by ether raises the question as to whether this portion represents an intermediate product in the inactivation of oestrin. In this connexion the results recently described by Silberstein, Engel, and Molnar (1933) are of great interest. These observers incubated oestrin with blood or liver tissue and found that by this method the hormone became rapidly destroyed or inactivated. Moreover, at one stage of this process they were still able to demonstrate the presence of a large proportion of the oestrin by the injection of the material into the ovariectomized animals; yet if this same material was extracted by means of an alcohol-acetone method a much smaller amount of oestrin was obtained. Later on, neither the material itself nor the alcohol-acetone extract contained any active oestrin. These results thus appear to show that *in vitro*, too, oestrin rapidly becomes inactivated, and that one of the intermediate products in the process of this inactivation is a form of the hormone not extractable by lipid solvents.

The finding that substantial amounts of oestrin may be excreted in the urine several years after the cessation

of menstruation appears highly interesting in relation to the genesis of the menstrual cycle. It is unlikely that the hormone found in the urine was ingested with the food, as comparatively large quantities of oestrin would need to be administered through the alimentary canal to give the rate of excretion observed. It must, however, be emphasized that in those post-menopausal cases in which oestrin excretion was found the urine was hydrolysed previous to the ether extraction, so that it is impossible to say whether any of the hormone originally present in the urine was in an ether-extractable form. This problem requires further investigation.

Lastly, the question arises as to the significance of the data so far obtained by a number of observers on the oestrin content of various body fluids and excretions. Where the material is directly injected into the ovariectomized mice (or rats), an assay of the total oestrous hormone content is presumably obtained. In those cases, however, where extraction of the material has been undertaken previous to the assay, results relating only to the hormone soluble in that particular solvent will be obtained, unless hydrolysis has also been performed. It may be urged that data relating to a definite form of oestrin (in so far as the solubility is concerned) are of more significance than the total quantity of oestrin-inducing hormone—that is, active in ovariectomized animals—present in a particular body fluid or excretion, and this may well be. On the other hand, the possibility that the rate of inactivation of the hormone may vary in different circumstances, physiological or pathological, and that the activity of the hormone in the body under normal or abnormal conditions may in part be determined by the rate of its inactivation, cannot be ignored, and further exploration of this aspect of the question appears to be necessary.

SUMMARY

Known doses of ketohydroxyoestrin have been injected intramuscularly into subjects, ovariectomized, or subsequent to the onset of the menopause, and the excretion of the hormone in the urine subsequently determined. It was found:

1. That only a small proportion of the oestrin administered could be recovered from the urine.
2. That a proportion of the hormone excreted was not extractable by ether. (This also applies to the oestrin excreted in normal pregnancy.)
3. That the blood of injected subjects contained less than one mouse unit of oestrin in 40 c.c.m.

Incidentally it was also established that substantial amounts of oestrin may be excreted in the urine even eighteen years after the menopause.

The expenses of this investigation were in part defrayed by a grant from the Medical Research Council to one of us (J. M. R.).

A CRITICISM OF ANTE-NATAL WORK*

BY

A. J. WRIGLEY, M.D., F.R.C.S.

SURGEON IN CHARGE OF OUT-PATIENTS, GYNAECOLOGICAL DEPARTMENT,
ST. THOMAS'S HOSPITAL

The genesis of ante-natal supervision as a recognized branch of preventive medicine appears to be associated with the name of the late J. W. Ballantyne, and to date from about the year 1902. Its value, however, can only be assessed with any pretence at accuracy over the last ten years, and, indeed, many competent judges question whether it has as yet received a fair trial. Be this as it may, it might with reason be expected that ante-natal supervision has been carried on to such an extent over this period of years that some results might by now be apparent in the figures of the national maternal mortality. Up to the present, however, no impression has been made on these figures, and if any change has occurred in the last few years the mortality has shown a slight rise. This fact has been a great disappointment, and has been the incentive for the production of papers of criticism and committees of inquiry. The published articles are not numerous, and, with one notable exception, devote themselves almost entirely to a debate upon the advantages and disadvantages to the community of the clinic system of ante-natal supervision.

SCOPE OF PRESENT REVIEW

In this criticism of ante-natal care an attempt will be made to review the actual work as it is being done to-day. If pre-natal supervision is unsatisfactory, or is actually wrong in its conception and execution, it matters not one jot or tittle whether it be performed by midwife, general practitioner, obstetric specialist, or by the medical men and women in charge of the twelve hundred or more ante-natal clinics that have appeared in the last few years. It is assumed that all are in agreement that medical supervision of the woman in pregnancy is a most admirable thing, and constitutes a definite advance in medical science. Ballantyne in 1923, in a lecture at Nottingham, expressed his opinion that ante-natal care might be expected to result in the removal of the fear and dread of the confinement and of much anxiety and suffering, and also in the early and more satisfactory treatment of toxæmia, syphilis, and cardiac diseases associated with pregnancy, etc.

The aims and objects of this branch of preventive work are well expressed by Fairbairn in his textbook *Gynaecology with Obstetrics*, and read as follows:

- "(1) To maintain the pregnant woman in health of body and mind.
- (2) To preserve the pregnancy to its full time.
- (3) To foresee and avert preventable difficulties and complications in labour and afterwards.
- (4) To secure the best provision possible for the labour, prepare the woman for the nursing and care of her child, and educate her in the care of her own health and that of her family."

Fairbairn continues with the warning that "some enthusiasts have run the new thing to death, and their examinations have tended to make the patient think her condition pathological rather than physiological."

A consideration of the subject will be made upon the above lines. It is impossible to discuss all the illnesses that can complicate, or be complicated by, pregnancy, and therefore a selection has been made.

THE TOXAEMIAS

Toxic albuminuria occurs in about 5 per cent. of all cases. Apart from the immediate possibility of pre-eclampsia and eclampsia, it is only in recent years that the added danger of permanent renal damage following this condition has been demonstrated by Young,¹ Gibbard,² and others. While the death rate from toxic

* The substance of a British Medical Association Lecture given to the Norfolk Branch on April 18th, 1934.

albuminuria and eclampsia shows an apparent slight fall during the last few years, the adjustment that is necessitated by a falling birth rate denies any real improvement. The conclusion must be reached that, taking the country as a whole, ante-natal supervision has failed to reduce the maternal death rate from eclampsia and allied conditions.

A consideration of the incidence of, and death rate from, eclampsia among the booked cases of certain obstetric hospitals shows another side to the picture. Thus there were only six cases of eclampsia in the last 7,000 women whose pregnancy was supervised at the General Lying-In Hospital, York Road, and, similarly, only three cases out of the last 3,500 women under the care of the Clapham Maternity hospital. This represents six years' work at both institutions. Every case, with one exception, was of a mild character, and in this series not a single patient died. These results owe something, at any rate, to a thorough, conscientious ante-natal supervision. That eclampsia is certainly not a preventable disease, however, is suggested by a recent case at St. Thomas's Hospital. A primigravida was examined at 10 o'clock in the morning. She felt perfectly well, and urine and blood pressure examinations showed no abnormality. Eight hours later she had an eclamptic fit.

Gibberd has shown that the incidence of "occult nephritis," which follows prolonged, untreated, perhaps symptomless toxic albuminuria of pregnancy, would show an even more striking decrease under similar conditions. There seems to be no doubt that the investigation and treatment of these cases of toxic albuminuria, whether they be of a chronic or of an acute type, is not adequate. The conscientious doctor not only examines the urine and blood pressure at regular and frequent intervals, but he instructs the patient, and makes certain that she understands the instructions, in the warning symptoms of this condition. In addition, he remembers those patients who neglect their routine visits, and does not excuse this negligence on the assumption that "no news is good news." The conscientious clinic behaves in exactly the same manner.

That our supervision in this direction is utterly inadequate is demonstrated in the findings of the Departmental Committee on Maternal Mortality. Out of 544 women who had died from eclampsia there had been no examination of the urine in 277, and in a further 120 who had been examined there had been no treatment. Results worse than these would be forthcoming if the figures were available for the less dramatic, and therefore apparently milder and less dangerous, toxic albuminuria of pregnancy.

Therefore we may certainly conclude that, taking the country as a whole, in the detection, supervision, and treatment of the condition of toxic albuminuria of pregnancy there is no question that this supervision is excessive, and considerable evidence that it is quite inadequate, and, as a general rule, is performed in so perfunctory a manner as to be useless.

HEART DISEASE AND PULMONARY TUBERCULOSIS

Good work is being done by ante-natal supervision in the detection and treatment of various conditions that have been complicated by the pregnancy—for example, chronic heart disease. The same remarks apply to the detection of the case of chronic nephritis, in which the renal function has broken down early in the pregnancy and has been treated successfully by an immediate induction of abortion.

Expert opinion is divided as to the best course to take in pregnant women who suffer from pulmonary tuberculosis. The detection of syphilis is difficult. It is usually discovered in the routine examination of a woman who is suspected to be suffering from a gonococcal infection, or whose past obstetric history warrants the examination of the blood. One might mention here the unwarrantable enthusiasm of the medical officers in charge of clinics in which every woman has the Wassermann reaction performed and the cervical secretion examined for gonococci.

THE WOMAN'S "HEALTH OF MIND"

Until a comparatively recent date a woman's attitude to her first pregnancy might be summed up, probably with

considerable accuracy, as follows. She realized, perhaps with pride, that she was doing what was expected of her, and that her forthcoming ordeal had been the lot of countless women before her. She was philosophical about it, and received some good and bad advice from her mother, her doctor, and one or two friends. There would doubtless be considerable discomfort, but with average luck she would survive. Lately the situation has changed. Long before she is even pregnant the woman has been educated up to the horrors of childbirth.

Thus, few of our novels to-day, with perhaps the exception of detective stories, acquire a good sales record unless they contain at least one detailed description of a labour, and this is usually a complicated labour. The daily papers and weekly periodicals—especially those for women—have frequent reference to the same subject. Some, with the most worthy object in view, and claiming that they only supply what the public demands, regularly devote a page to the mysteries of pregnancy and labour. Enough is written only to produce an element of doubt as to the safety of the process, and to leave no doubt as to the many dangers. The stage and screen do their part thoroughly in a like manner. The anxious husband, the nurses and doctors, the closed doors, all successfully portray the tense atmosphere of impending disaster. How does our ante-natal supervision react to this? The answer is, in the vast majority of cases, "Not at all." Perhaps an occasional question is asked as to whether our patients have any worries, and at that the question is dropped. If sensible inquiries were made on these matters an untold amount of fear and anxiety could then be avoided. Possibly the picture has been somewhat exaggerated, and applies only to a proportion of our patients, but the faith in the hospital and the better education of women at the opposite end of the social scale goes a long way to negative any harm that may be done in the manner suggested.

DISPROPORTION: THE PROBLEM OF INDUCTION

In pregnancy the detection of the major degrees of pelvic contraction can only be of the greatest benefit to the patient. The management of the minor degrees of disproportion as a result of ante-natal observations presents a sad picture. Even the teaching upon this subject is in a state of the utmost confusion. There are some schools which advocate the induction of premature labour at any time after the thirty-second week of pregnancy, others which say that this treatment results in such a high foetal mortality that, in the long run, Caesarean section is the best, and still others which, stating that the majority of inductions done for this condition are unnecessary, advocate a trial labour. The relative merits of these various methods do not concern us in this discussion.

At the present time, however, in the vast majority of cases, the treatment of minor degrees of disproportion between the foetal head and the pelvic inlet resolves itself into "Induce if there is any doubt." This assumes two things: first, that failure to induce will result in disaster, probably to the mother and certainly to the child, and, secondly, that induction is for practical purposes free from all risk.

This aspect of ante-natal work was most ably debated by Professor Browne^a in a recent paper. He analysed the causes of maternal death in the booked cases of several obstetric hospitals, and showed that no fewer than one in twenty of these deaths occurred as a result of induction of labour. He states that "It is no help to anyone who is rescued from the hypothetical consequences of an abnormality and is killed in the rescue..." and points out that this simply means that ante-natal supervision transfers the mortality from one column to another.

There has been no mention as yet of the complications of induction of labour other than the death of the mother. In the case of the mother the insertion of bougies is followed by such complications as rupture of the membranes, which is a serious matter in a possible case of dystocia, or by separation of the placenta, or by puerperal infection, or—and this is probably the most serious of all—by failure to induce the labour. To the child the results are even more disastrous.

HOSPITAL STATISTICS OF INDUCTION

The following information has been collected from the obstetric departments of five hospitals. The infant mortality in some 1,600 cases in which labour was induced for minor degrees of disproportion was just under 10 per cent. This figure is probably fairly accurate, as it varies but little in the different hospitals.

Thus, Hospital A	8.2 per cent.	infant mortality.
" B	12.0 "	" "
" C	8.1 "	" "
" D	10.3 "	" "
" E	8.9 "	" "

It may be argued that without the ante-natal supervision and consequent detection of the "minor degree of disproportion" these figures would be greatly increased. This apparently obvious conclusion is probably erroneous. In how many of these cases did there exist that "minor degree of disproportion" that necessitated a premature termination of pregnancy?

The presence or absence of moulding of the foetal skull, when examined after delivery, can be regarded as an accurate index of the existence of any disproportion. An analysis of the incidence of this moulding could only be found in the records of two hospitals, but the figures obtained can be accepted, in all probability, as a fair average. Out of nearly 200 consecutive recorded cases the moulding of the foetal skull was noted to be excessive in 9 per cent., marked in 38 per cent., slight in 42 per cent., and absent in 11 per cent.

This means that in over 50 per cent. of cases the induction of labour was performed unnecessarily. This figure is almost certainly extremely generous to the country as a whole, for the medical staff attached to the hospitals concerned are most conservative, and induction, like all other intervention, is kept at a much lower level than was to be found when comparison was made with the figures obtained from the obstetric departments of other institutions.

The next point to appreciate is that the 10 per cent. of foetal deaths were by no means due to excessive compression of the foetal skull and intracranial haemorrhage. In only about one in three of the infants that were stillborn or died shortly after birth had intracranial haemorrhage occurred, and in nearly 50 per cent. of cases the prematurity or atelectasis appeared to be the cause of death. Further, the mortality was actually greater in those infants where the moulding was noted to be slight or absent than in those where the moulding was marked or excessive. These figures were obtained from the records of only one of the institutions included in the list quoted above.

Lastly, a consideration must be made in the enormous variation in the apparent necessity for any interference with the pregnancy. This would no doubt be found to be most noticeable were a comparison to be made of the practices of individuals, but these figures are difficult to obtain. A comparison of the practices of different hospitals is equally instructive. All the following results are taken from the booked cases of the institutions concerned. Thus it is found that the percentage of all booked cases requiring treatment for minor degrees of disproportion:

	By Induction	By Caesarean Section
Hospital F	1.6 per cent.	0.8 per cent.
" G	3.6 "	0.3 "
" H	1.6 "	0.1 "
" I	0.25 "	No cases

It will be seen that in Hospital G fourteen times as many cases are thought to require induction of labour as in Hospital I, and that in this last hospital no case was treated by Caesarean section, whereas in Hospital F this operation appeared to be necessary in nearly one in every hundred cases seen. All these institutions are in London, they are all staffed by men and women who can be classed as obstetric specialists, and it may be assumed that there is no great variation in the size of the babies or in the skeletal structure of the mothers.

IS IT PERFORMED UNNECESSARILY?

The facts that have just been recorded can lead only to the following conclusions. Ante-natal supervision has resulted in the erroneous diagnosis of a minor degree of disproportion in an enormous number of women in whom it did not exist. As a result, unnecessary treatment by induction of labour with bougies or by Caesarean section was performed. This treatment, which is designed to save mother and child from what has been demonstrated as only a problematically difficult labour, is in itself not without danger to the mother. Further, it results in a 10 per cent. mortality to the infants, and this mortality is due not so much to the tight fit of the head as to the inability of a premature child to keep a hold on life after delivery. The facts do not of necessity signify that our treatment of this condition is wrong in its conception. It is suggested that they indicate rather that ante-natal supervision, in its anxiety to find a possible abnormality, has tended to overlook the extreme difficulty of its diagnosis and to underrate the consequences of treatment. We must ask ourselves the question "Need we induce?" not "Can we induce?"

EXTERNAL CEPHALIC VERSION

Consideration will now be given to another preventable difficulty and complication. The external cephalic version of a breech presentation is usually accepted as an undisputed triumph for pre-natal care. By this manipulation the mother can be saved from what may turn out to be a long and difficult labour, in which delivery has to be completed by manipulations which may be prolonged and dangerous. To the baby the birth as a breech presentation has added dangers in that it may die of asphyxia resulting from compression of the umbilical cord, or premature inspiration, or that the too rapid delivery of the foetal head may cause intracranial haemorrhage. Surely, then, external cephalic version cannot do anything but good?

The present teaching on the subject is, put shortly, as follows. If a breech presentation is discovered, look for a possible cause for the malpresentation. Should none be found, perform a cephalic version at any time during the last four weeks of pregnancy. If the external version cannot be done without an anaesthetic it is certainly justifiable, if not advisable, to give an anaesthetic.

This advice and teaching is followed only half-way in one direction and with too great an enthusiasm in another. It is practically never that anything but good results from a gentle version. When the patient is anaesthetized our anxiety to correct the malposition may be such that, no longer restrained by any discomfort to the patient, we may do actual harm.

During the last two years at two London obstetric hospitals some seventy-six patients were anaesthetized in pregnancy for the purpose of correcting a breech presentation. The version was successful in forty-five instances, in so far as a vertex presentation was obtained. *Only thirty-five of the babies were born alive.* The remaining ten were stillborn, usually macerated. Movements had been felt and the foetal heart heard prior to the version. In some instances the efforts to turn the baby had caused rupture of the membranes, in one woman the cord prolapsed, and on three occasions there was a brisk ante-partum haemorrhage. The foetal deaths were caused by asphyxia of the baby owing to detachment of the placenta or constriction of the umbilical cord, as a direct result of somewhat violent efforts to turn the baby. It is an ironical fact that at one of the hospitals version failed in nineteen cases, and all of these women subsequently were delivered of a healthy living child, as a vertex presentation in eight instances. Thus when external cephalic version is performed under anaesthesia there seems to be an infant mortality in the region of 13 per cent.

Gibberd* showed that the foetal death rate in uncomplicated* breech deliveries was about 28 per cent. in

* That is, not complicated by contracted pelvis, placenta praevia, pelvic tumours, etc., but including those cases in which the baby has extended legs and arms.

primiparae and 15 per cent. in multiparae, but the same institution whose ante-natal work practised the version under anaesthesia of breech presentations with an accompanying stillbirth rate of 13 per cent. delivered successfully in the last five years some seventy breech cases, with an infant mortality of only 10 per cent. In the above series about 50 per cent. of the patients were primiparae, as regards both version and delivery. It is apparent, therefore, that external cephalic version under anaesthesia must be regarded as a manipulation that is not free from danger and that must not be performed with the use of any force.

The other aspect of the pre-natal care of this malposition is in the opposite direction. The two phrases "breech presentation" and "cephalic version" appear to be so intimately related in the minds of the majority of those who practise obstetrics that the real significance of the condition is generally overlooked. When the malposition is found it should first be regarded as a probable warning sign of such serious complications as a flat pelvis, placenta praevia, a pelvic tumour, etc. Instead, these possibilities are too often forgotten and overshadowed by the importance of correction. This state of affairs does not exist, for some reason or other, in the case of the transverse lie. When the child is found to lie thus it is widely appreciated that a careful search should be made for a cause, and that the correction is of minor importance.

The face presentation is hardly ever diagnosed before the onset of labour, and the pre-natal treatment of the occipito-posterior position has gone out of fashion. It may be remarked that the incidence of this position of the foetus at the commencement of labour was exactly the same at the General Lying-In Hospital, York Road, in the days when the Biist binder was carefully and regularly applied, as it has been these last few years, when the treatment has been discarded.

ANTE-PARTUM HAEMORRHAGE

Pre-natal care can only influence the "accidental" variety of ante-partum haemorrhage in those cases that appear to be caused by a toxæmic condition. Much good work has been done in the detection of placenta praevia. In pregnancy a woman would always report to her doctor the occurrence of haemorrhage, however slight it might be, and instruction to do so is almost superfluous. Not infrequently cases of central or marginal placenta praevia are diagnosed in consequence of the discovery during a routine examination of some abnormality. The presence of a persistent malpresentation—for instance, an oblique lie of the child that resists all efforts at correction—or a breech presentation, or, again, a foetal head that will not engage, although it is known that the pelvis is normal and the baby's head not too large, all suggest the possibility of this serious complication. A final diagnosis is arrived at when a pelvic examination reveals a mass of tissue between the fingers in the vagina and the presenting part of the foetus. Radiographic methods have lately been demonstrated to be of practical assistance in establishing the site of placental implantation. Ante-natal care is doing good work in this direction, and but little criticism can be made.

CARE OF THE BREASTS

Space will not allow of more than a few passing remarks upon the last section, where pre-natal care is charged with the duty of preparing the woman for the care of her child. Like some branches of this work, the preparations for breast-feeding are either completely neglected or grossly exaggerated. Of these two evils the former is much to be preferred, as it does no actual harm. This variation in practice is largely the result of variation in teaching. The discovery and treatment of retracted nipples before the birth of the child makes all the difference between the probability and impossibility of breast-feeding. Most of the patients understand the reason that the treatment is necessary, and co-operate willingly. Excessively enthusiastic pre-natal care in this direction orders the sponging of a supposedly inactive breast alternately with hot and cold water two or three times a day, and probably, in addition, the application of some ointment or spirit to the skin of the nipple, or even the use of a nailbrush is advised. This latter practice is to be condemned, as definite physical harm can be done. In ordering such treatment no consideration can have been given to the way in which the patient's mental attitude can influence

the success or failure of breast-feeding. Excessive and unnecessary attention to the breasts in pregnancy will, in an appreciable proportion of women, produce a real antipathy to the prospect of breast-feeding. This criticism of ante-natal supervision is unnecessary to those of us who have the care of our patients throughout the whole of pregnancy, labour, and the puerperium, but is intended rather for those in charge of ante-natal clinics and who are unfortunate in that they are not given the opportunity to judge the results of their handiwork.

ATTITUDE OF DOCTOR, MIDWIFE, AND PUBLIC HEALTH AUTHORITY

Lastly, let us spend a few moments in consideration of the attitude of those who participate in this work. The patient comes first. The great majority of women realize that the supervision of pregnancy is necessary and likely to be of benefit to themselves and to their babies. The others, a small minority now, do not think about it at all, and agree to the repeated examination as a necessary evil. Midwives, like doctors, are good, bad, or indifferent. The good midwife is extremely efficient and balanced in the care of her patients in pregnancy. The indifferent or bad midwives either neglect this side of their work or load it on to the neighbouring municipal ante-natal clinic. As the success or failure of the work of these clinics is largely gauged by the numbers that attend, this too frequently is overlooked. The medical practitioner realizes that ante-natal supervision is an excellent thing. He, and she, plod along, doing the best they can in the circumstances, somewhat bewildered by the great variation in treatment of abnormalities prescribed by the obstetric experts, and greatly discouraged by the almost invariable condemnation of their efforts. As has been said before, there are good doctors and bad doctors, but it seems that too often all are assumed to be bad. The medical student usually takes an intelligent interest in the work, but, as in the other branches of his medical curriculum, he is seldom made to realize that there is such a person as a patient, who is a woman with the cares of husband and home upon her shoulders. He learns about the early diagnosis and management of toxæmia of pregnancy, and his successful diagnosis of twins or a breech presentation gives him great satisfaction. His sense of proportion becomes more balanced when he starts his practice.

The public health authorities, in their extremely worthy efforts to educate the prospective mothers of the country, have undoubtedly exaggerated—in some instances grossly—the benefits that can accrue from ante-natal supervision. Instead of stating the facts somewhat as follows: "Attend the ante-natal clinic, and you may thereby hope to prevent some of the abnormalities that may occur in your confinement," the propaganda has rather been upon the lines, "Attend the ante-natal clinic, and you will thereby ensure for yourself a normal pregnancy, labour, and puerperium." The clinic is tending to become inviolable. Should something untoward happen in the labour, or puerperium, or even in the pregnancy for that matter, and the family doctor is called in, he too often receives, entirely undeservedly, any censure that is meted out by the family for the subsequent illness or death of the mother or child.

CONCLUSION

Those who practise the art of midwifery have seen that ante-natal supervision as it is being done to-day cannot accomplish all, nor yet half, what has been claimed for it. The pendulum has swung too far. The search for the abnormal has masked the preservation of the normal, and the pregnant woman receives a mixed blessing. There is probably more significance than was intended in the words of the Final Report of the Departmental Committee on Maternal Mortality: "It is essential that ante-natal care should reach the highest possible standard of excellence."

Clinical Memoranda

A CASE OF MIXED LEUKAEMIA

Cases of "mixed" leukaemia are rare, and although there may be some doubt as to the correctness of the terminology, they are of considerable clinical and haematological interest.

The patient, a woman aged 28, gave a history of having had an attack of "influenza" in March, 1928, from which she never fully recovered; weakness and lassitude persisted, and in December, 1928, pallor was noticed by her relatives. On June 14th, 1929, she had an attack of tonsillitis, followed by right basal pneumonia, jaundice, and albuminuria. The temperature became normal in seven days, and no further rise occurred. A short time afterwards she developed a laryngeal cough and dyspnoea, and the cervical lymph glands became enlarged.

On August 1st, 1929, anaemia was marked, and there was general enlargement of all the superficial lymph glands. The liver was palpable two inches below the costal margin, and the spleen three inches below the costal margin. There was no jaundice or petechiae. The blood count was: haemoglobin, 20 per cent.; red cells, 1,800,000 per c.mm.; white cells, 494,000 per c.mm.; colour index, 0.5. In stained films normoblasts and polychromatic and punctate basophilic red cells were frequently encountered, with an occasional red cell containing Howell-Jolly bodies. Many macrocytes were present. A differential count of 8,000 leucocytes was:

Small lymphocytes	...	372,723 per c.mm.	75.45 per cent.
Large lymphocytes	...	55,575	11.25
Polymorphs	...	21,489	4.35
Eosinophils	...	494	0.1
Basophils	...	247	0.05
Monocytes	...	494	0.1

Myelocytes (including pro- and meta-myelocytes):

Neutrophil	...	23,465 per c.mm.	4.75 per cent.
Eosinophil	...	1,482	0.3
Basophil	...	741	0.15
Myeloblasts	...	14,326	2.9
Normoblasts	...	2,964	0.6
		494,000	100.00

The percentage of oxidase negative cells corresponded closely to the lymphocyte count.

The patient died on August 22nd, 1929. Necropsy was not allowed.

The criteria of a diagnosis of "mixed" leukaemia were laid down by Browning¹ and Von Domarus.² They considered that such a diagnosis could only be justified if, in the organs, hyperplasia of both myeloid and lymphoid tissue occurred side by side, and that this hyperplasia occurred simultaneously. These standards could not be satisfied, but this does not detract from the clinical interest of the case. The history does not correspond to the blood findings. The short history of glandular enlargement—ten weeks before death—suggested an acute leukaemia, but the basic blood picture was that of a chronic lymphatic leukaemia. There was no evidence of sepsis on August 1st to account for the marrow reaction, nor is it recorded that such a degree of myelocytæmia with the large number of myeloblasts and normoblasts seen in this case occurs in sepsis.

That cases of true mixed leukaemia do occur is undoubted. Logeheil,³ reviewing the cases published up to 1924, states that:

"Although myelocytes may be found in the blood when any great demand is put on the bone marrow, promyelocytes and myeloblasts never appear unless there is a definite specific stimulation of the bone marrow or extramedullary organs, such as is found in myeloid leukaemia. The same can be

said in reference to the lymphocytes in myeloid leukaemia, for although lymphocytes are found in the blood the immature forms are not found unless there is stimulation of the lymphatic tissue similar to that producing the activity of the myeloid tissue."

Generally speaking, I think these statements true, and it is a matter of surprise and speculation that the various leukaemias, acute and chronic, should be so sharply defined in their blood pictures and histology. Whatever the cause of leukaemia, the abnormal state appears to be specific for each type of haemopoietic tissue in the vast majority of cases, and it is reasonable to suppose that in cases of mixed leukaemia two such states are present, as they appear to have been in this case.

EXTENSIVE DIPHTHERITIC PARALYSIS WITH COMPLETE RECOVERY

The following record of an unusually severe case of diphtheria may interest some members of the profession, as it indicates to what extremes a patient may develop diphtheritic paralysis and yet recover completely. At the same time I set forth the medicinal treatment which was given, and would particularly draw attention to the dose of diphtheria antitoxin which was administered when the patient was in *extremis*. I do not claim that at such a very late stage of diphtheria credit can be given to this dose, but certainly there was a very rapid clearing up of the various types of paralysis within a few days of the injection.

The patient, a girl of 13, was admitted to Clifton Hospital, Brighouse, on November 15th, 1933, as a severe case of faucial diphtheria in her fifth day of illness. Her previous history of infectious diseases was that she had had scarlet fever, measles, chicken-pox, and whooping-cough. The present illness dated from November 11th, when she had sore throat and nasal discharge: enlarged neck glands were also noted at this time. On admission she was found to be of good muscular development and well nourished. Her skin was free from rash. The neck was considerably enlarged on both sides, with tissue infiltration of the "bull-neck" type. The tongue was coated, the fauces very inflamed, and the tonsils enlarged and practically meeting in the middle line, pushing forward the uvula. Membrane covered the front of the tonsils and uvula, and one surmised that there was a considerable amount on the posterior aspect of the swollen tonsils. The heart sounds were good, but there were occasional missed beats. The lungs showed nothing abnormal. The temperature was 97.6° F., pulse 80, and respirations 22. The family practitioner mentioned the very rapid extension of membrane, and at the earliest opportunity had injected 32,000 units of diphtheria antitoxin. In hospital, on admission, I gave 18,000 units of antitoxin intravenously, and 30,000 units intramuscularly. The total dose of serum by the fifth day was therefore 62,000 units intramuscularly, and 18,000 intravenously.

From this time her illness took the following course.

Sixth Day.—Slight rise of temperature to 99° F.; pulse 110; respirations 28. One drachm of brandy given four-hourly.

Seventh Day.—Slight vomiting of light-brown-coloured fluid. Maximum temperature 99.6° F.; pulse 120; respirations 28. Peptonized milk given. Taking fluids well. Brandy discontinued; camphor in oil, 1 c.cm. (1½ grains in 1 c.cm.) substituted eight-hourly.

Eighth to Twelfth Days.—Temperature subnormal to normal; pulse rates diminishing from 110 to normal; respiration rates diminishing from 32 to normal. Vomiting gradually ceased. Taking fluids well. Camphor in oil discontinued on tenth day.

Thirteenth Day.—Extrasystoles detected after every eighth or tenth beat. Temperature normal; pulse 80; respirations 20. Taking a little bread-and-butter, chicken tea, and chicken jelly.

¹ Browning, C.: *Lancet*, 1905, i, 507.

² Von Domarus: *Folia Haematol.*, 1908, vi, 357.

³ Logeheil, R. C.: *Arch. Int. Med.*, 1924, xxxiii, 684.

Fourteenth Day.—Extrasystoles less marked. Pulse rate still 80.

Fifteenth Day.—Cardiac beats regular. Pulse rate 80.

Sixteenth Day.—Fairly satisfactory. Eating more.

Seventeenth Day.—Pain in left shoulder extending down back of left arm; nothing definite to detect; ung. iodox applied.

Eighteenth Day.—Temperature slightly subnormal; pulse 100; respirations 22. Nasal intonation, and defective movement of soft palate.

Nineteenth to Twenty-First Days.—Fairly satisfactory apart from palatal paralysis.

Twenty-Second Day.—Temperature slightly subnormal; pulse 98; respirations 22. Duplication of first sound at apex, and occasional hurried beats. Liq. strych. hydrochlor. prescribed—1 minim three times a day.

Twenty-Second to Twenty-Sixth Days.—Cardiac beats at first very irregular, but later more regular. Liq. strych. increased to 1½ minims three times a day.

Twenty-Seventh Day.—Cardiac beats still more regular. Liq. strych. increased to 2 minims three times a day. Pulse rate during last few days about 100.

Twenty-Seventh to Thirty-Second Days.—Cardiac beats steadier. Pulse rate still about 100.

Thirty-Third Day.—Cardiac beats regular, but marked pulmonary systolic murmur. Pulse 94.

Thirty-Fourth to Forty-Second Days.—Pulse rate varying from 92 to 100, but quite regular. Liq. strych. discontinued.

Forty-Second Day.—Paresis of lower limbs; absence of knee-jerks; defective sensation; complained of "pins-and-needles" in hands; partial loss of co-ordination in upper limbs. Abdominal reflexes +. Still very nasal. Liq. strych. recommenced with 1½ minims three times a day.

Forty-Second to Forty-Fifth Days.—Condition remained as above.

Forty-Sixth Day.—Complained of double vision; no evidence of squint. Coughing after food, with tendency to regurgitation, indicating paralytic involvement of pharynx.

Forty-Seventh to Forty-Ninth Days.—Coughing more pronounced after food.

Fiftieth Day.—A few moist rales in chest. Ordered frequent changes of position. Liq. strych. increased to 3 minims three times a day.

Fifty-First Day.—Difficulty in breathing; numerous adventitious sounds in chest. Later in day diaphragmatic paralysis with considerable difficulty in breathing. Extraordinary muscles of respiration brought into play, with a tendency for these to fail at times. Heart sounds at first regular and good, but later very feeble. Patient in *extremis*. Frequent vomiting. Liq. strych. discontinued, as patient unable to swallow. Camphor in oil substituted, 1 c.c.m. every four hours. Kataplasma kaolin applied to chest.

Fifty-Second Day.—Condition as above, with cessation of breathing at times. Frequent vomiting. Glucose enemata administered. Incontinence of bladder and bowels; 12,000 units of diphtheria antitoxin injected intramuscularly, patient first desensitized with 0.5 c.c.m. dose, and remainder given after four hours.

Fifty-Third Day.—Condition remaining the same.

Fifty-Fourth Day.—Paralysis of right external rectus muscle of the eye; defective reaction of both pupils to light and on accommodation. Paralysis of neck muscles. Vomiting ceased. No difficulty in swallowing. Taking a little fluid. Camphor in oil discontinued.

Fifty-Fifth Day.—Soft palate showing movement. Nasal intonation somewhat improved. Power of respiratory muscles regained; breathing quietly and normally. No difficulty in swallowing. Taking more fluid. Control over bladder and bowels. Heart sounds good.

Fifty-Fifth to Sixty-Sixth Days.—All forms of paralysis gradually cleared up, and from this time until her discharge from hospital on March 10th, 1934, in her one hundred and twentieth day of illness she did well, apart from a slight follicular tonsillitis on her ninety-third day.

To sum up, in this case there was definite evidence of paralysis of the palate, lower limbs, pharyngeal muscles, muscles of respiration, external muscle of the right eye, and neck muscles, with partial paralysis of the cardiac muscle, muscles of the upper extremities, and ciliary muscles of the eyes, or iris, and, possibly, although one cannot be definite, paralysis of the oesophagus and sphincters of the bladder and bowel. On discharge she had completely recovered, and all that could be detected was a faint pulmonary systolic murmur, possibly of a haemic nature.

Brighouse Joint Hospital Board.

Reviews

DISEASE AND HEREDITY

Last year the Buckston Browne prize was awarded to Dr. L. S. PENROSE; and his prize essay, slightly amplified, has now been published under the title of *The Influence of Heredity on Disease*.¹ It is an important and valuable study on a subject a knowledge of which becomes more and more indispensable to the medical practitioner. It cannot be described as exactly simple and elementary, but to those who have a fair acquaintance with biological principles and some knowledge of medicine and of genetics it forms as good an introduction to a further understanding of the relations between these last two spheres as could be obtained. It is arranged in four sections. The first deals historically with the development of genetical concepts, tracing them through Lamarck and Darwin, Mendel and Galton, to Haldane and Hogben. This survey is brief yet clear; and we find in it an illuminating illustration of the havoc played by scientific discovery on Sedgwick's statement that "leprosy is a thoroughly hereditary disease," and a well-timed destructive criticism of the popular beliefs that types of inheritance other than the Mendelian play an important part in human genetics; and that nature eliminates tainted stocks by increasing the severity of the taint in succeeding generations.

In the second section modern methods of research in human genetics are discussed, with special reference to disease, and in the third section examples of genetical analysis by such methods are detailed. Readers without knowledge of mathematical methods and reasoning may not be able, except by considerable effort, to follow this analysis, but the intelligent reader can scarcely fail, in any case, to realize the main points illustrated, the complicated nature of the relevant data, the pitfalls into which the unwary may so easily stumble, and the great practical importance, both negative and positive, of the results which may, with due care, be regarded as reasonably established. These results and conclusions are summarized in a final section. As the author says: "Few members of the medical profession have, at the present time, appreciated their full implications." We are reminded how extremely tempting it is to assume, when no cure for a disease is known, that its origin is hereditary, but that "it is not sufficient to establish the fact of the occurrence of a disease in various members of a family group in order to prove that the disease in question is hereditary," and that "statements ascribing indefinite hereditary causes to pathological conditions before a proper analysis has been made are misleading and liable to retard the progress of serious research." The relative influence of environment and heredity must be continually borne in mind. Even though the results of recent research in this field have been brilliantly successful, and even though there is every prospect that reliable data will become more and more available, "generally speaking, it is unwise to be unduly optimistic about the results of eugenic measures in medicine. There is no short cut to the control of the common scourges of humanity: . . . even though heredity may be an important aetiological influence in all of them." It is only in a few conditions in which the method of transmission is definitely known—and particularly in respect of dominant autosomal and all sex-linked characters causing severe disease—that "it may reasonably be held that prevention of offspring is a sound prophylactic measure."

REMEDIES FOR SYPHILIS

The excellent little book entitled "Anti-syphilitic Remedies" was written for the Belgian Scientific Library, evidently as one of a series of short works on medical subjects. Originally, Dr. R. WAUCOMONT was to have written the articles on arsenobenzol and bismuth, whilst Professor F. HENRIJEAN undertook that on mercury. Unfortunately, however, the latter died before the work was complete, but his collaborator obtained the original manuscript on the mercurials, annotated it, and so produced the full work.

The whole subject has been condensed into 184 pages, so that no complete study was possible, but the authors have concentrated mainly on the action of these remedies on spirochaetes and on the tissues, the normal and pathological reactions they produce, and the methods of dealing with the latter. The book falls into three sections—on arsenobenzol, bismuth, and mercury respectively. That on arsenic is the best. The pros and cons of the various preparations are well set out, some preference being shown for silver salvarsan as on the whole the most efficient. The question of such subjects as arseno-resistance and accidents due to salvarsan are most aptly discussed, while the cause of neuro-recurrences is definitely ascribed to too little arsenobenzol and not to too much. Bismuth and mercury are both more than adequately dealt with, and a leaning is shown towards the view that in recent times the latter has been rather overshadowed by the former, to the detriment of the patient. Not everyone will agree that the combination of arsenic and mercury is generally preferable to arsenic and bismuth, but that is a matter of opinion: the author does not favour concurrent treatment, but prefers to give a course of one drug followed by a course of another. The action of the three drugs, their absorption, elimination, indications, and contraindications, and the complications which they may cause, are all very clearly put in a fashion intelligible to tyro and expert alike. No section on iodides is included.

All who have to do with the treatment of syphilis, and consequently with the use of arsenobenzol, bismuth, and mercury, should make a point of reading this very valuable work. Nowhere else can he found so much reliable information on the subject condensed into such a small space. Those who cannot read French will be the poorer till an English translation appears—a consummation much to be desired. The work is well documented, references being given at the foot of the page.

HYPERTENSION AND NEPHRITIS

The third edition of Dr. A. M. FISHBURG's work on *Hypertension and Nephritis* follows with but little delay the previous edition in 1931, and, being essentially a wide review of recent advances, has been much and well revised. As is natural from the author's close association with the Mount Sinai Hospital, New York, the influence of Dr. Emanuel Lihman and his other colleagues is obvious, and is gracefully acknowledged. The earlier chapters deal with more general aspects, such as disordered renal function and tests for its estimation, albuminuria, oedema, and normal blood pressure, before going on to the consideration of the nephritides and the nephroses. Among the additions is a discussion of the part played by the pituitary, and especially by Cushing's basophilism, in the causation of essential hypertension, and here the cautious decision of "as yet unproven" is

adopted. With regard to the normal limits of blood pressure, the author considers systolic pressures above 150 and diastolic pressures of 100 and more millimetres to be pathological, and concludes that the typical blood pressure in healthy adults does not change with advancing years, but that in the older age groups there are more individuals with blood pressures approaching the upper limit of the normal, and that this elevates the average blood pressure; this carefully italicized dictum may at first sight appear to be rather a fine distinction, but it is probably sound. The structural change characteristic of the malignant phase of essential hypertension is stated to be the addition of necrosis and endarteritis of the renal arterioles; this is based on the examination of twelve cases by Dr. Klemperer at the Mount Sinai Hospital. The treatment of essential hypertension, which is admitted to be "one of the many unsatisfactory chapters in therapeutics," is considered in detail, and the volume closes with a section on renal and hypertensive disease in pregnancy.

YEAR BOOKS OF PRACTICAL MEDICINE

We have received the complete Practical Medicine Series of the 1933 Year Books, issued by the Year Book Publishers, Inc. (304, South Dearborn Street, Chicago), and obtainable in this country from H. K. Lewis and Co., Ltd. (Gower Street, W.C.1). This series, now in its thirty-third year, consists of ten volumes, devoted respectively to: general medicine; general surgery; urology; eye, ear, nose and throat; paediatrics; obstetrics and gynaecology; general therapeutics; neurology and psychiatry; dermatology and syphilis; and radiology. The material comprises a series of abstracts from current literature dealing with various aspects of each subject, and should prove useful for reference purposes. The volume entitled *Obstetrics and Gynaecology*, edited by Drs. Joseph B. DeLee and J. P. Greenhill, is some 600 pages in length, and includes a brief but good selection from the literature on pregnancy diagnosis by biological tests. There are frequent editorial annotations throughout the remainder of the text, the expression "Rah! Rah!" being at one point wrung from one editor as a favourable comment on the low cervical method of Caesarean section. *Urology* has a short editorial introduction by Dr. J. H. Cunningham, in which the need is emphasized for correlating genito-urinary disease with that in other parts of the body: reference is also made to the increased employment of caudal and regional anaesthesia. This volume is 430 pages in length. In *Eye, Ear, Nose and Throat* (600 pages), edited by Drs. Brown, Bothman, Shambaugh, and Hagens, all subjects are well covered, and occasional commentary is made in the text. Dr. Evarts A. Graham, who is responsible for *General Surgery*, remarks in his preface upon the increasing attention which is being paid to thoracic surgery in America. Other subjects singled out for mention are the use of mercurochrome, biopsy in suspected cancer of the breast, gastrostomy by the Janeway method, and the results of surgery in adenoma of the islet tissue of the pancreas. *Dermatology and Syphilology*, edited by Drs. Fred Wisé and Marion B. Sulzberger, is pre-eminently practical, special attention being devoted to such subjects as acne vulgaris, allergic manifestations, eczema, etc. A considerable amount of current foreign literature has been covered, and the supplementary bibliography provides opportunities for further exploration. Drs. P. Bassoe and F. G. Ebaugh are responsible for *Neurology and Psychiatry*. Among other things, they call attention to recent work on the Argyll Robertson pupil; to the continued disagreement on the treatment of head injuries in respect of lumbar puncture, hypertonic solutions, and indications for operation; to fever therapy; and to investigations on the endocrine

¹ Les Médicaments Antisyphilitiques. Par F. Henrijean et R. Waucumont. Paris: Masson et Cie. 1933. (P. 186. 20 fr.)
² Hypertension and Nephritis. By A. M. Fishberg, M.D. London: Baillière, Tindall and Cox. 1934. (Pp. 668; 40 figures. 82s. 6d.)

glands in relation to nervous disease. This volume is well illustrated, and runs into 433 pages. In the preface to *General Therapeutics* the editor, Dr. B. Fantus, mentions the recent change in views regarding the intimate mode of action of nerve-muscle poisons, and the use of acetyl- β -methylcholine as a parasympathetic nerve stimulant. Other aspects of therapeutics include bacteriophage; convalescent serum in poliomyelitis and septic scarlet fever; mercurial diuretics and calcium in thrombophlebitic oedema; glycocholl in myasthenia; dinitrophenol (with a warning); duodenal tube siphonage in acute intestinal obstruction; and, finally, the use of injection treatment in hernia and pruritus ani. This volume consists of 439 pages and includes a section on physical therapy.

EVERYDAY MEDICINE

General practitioners will welcome Professor BARKER'S book on *Treatment of the Commoner Diseases*,⁴ and those of the older generation who are familiar with, and admirers of, the writings and work of Oster will read with special interest this work of his successor.

The book is based upon a series of ten post-graduate lectures delivered in Ohio in the autumn of 1933, in which the author makes no pretence of discussing fully and completely any topic, but claims his freedom to make comments on any subject he considers "pertinent to general practice." Thus the book embodies the personal opinions of one who speaks with authority from long experience, and one who has read widely. The extent of his reading may be judged from the fact that within the compass of some 300 pages there are references to more than 1,000 authors.

The first chapter deals with advances in the methods of studying patients, and Dr. Barker notes in particular that studies in heredity have thrown new light on the "human constitution." He accepts the classification of constitutions on the basis of Kretschmer's work on physique and character—in which character formation as well as bodily structure are taken into account—distinguishes four main groups, and indicates how the practitioner may be helped through familiarity with these types to a better understanding of his patients and their predisposition to physical and mental disorders. The importance of the social, economic, and psychological conditions of the patient are not forgotten, and the practitioner is reminded that the problem of treatment has in many cases to be solved in relation not to a single disease, but to a group of disorders. Dr. Barker shares the view of many of his fellow countrymen that periodic health examinations are of very great value in the prevention and early detection of disease. In this respect he is preaching to the unconverted, for practitioners in this country have been slow to recognize the importance of such examinations.

The subsequent chapters deal with a considerable number of the commoner diseases, together with some rarely met with in general practice and a few surgical conditions. Several chapters begin with a short account of recent advances in knowledge, and this forms a valuable introduction to the treatment of the diseases that follow. The general excellence of the articles in which the treatment is discussed with a moderate degree of fullness makes it difficult to single out any for special mention, but note might be taken of the chapter dealing with circulatory diseases and that treating of metabolic and endocrine disorders.

In fairness it must be stated that there are some notable omissions in this book, and that several im-

portant diseases receive insufficient attention. For example, in the chapter on respiratory diseases chronic bronchitis and emphysema are not even mentioned, and the references to pleural inflammation, acute bronchitis, and bronchopneumonia are too short to be adequate. Again, the ketogenic diet treatment of chronic pyelocystitis is dismissed in a line and a half, and the new drugs, atabrin and plasmoquine, used in the treatment of malaria, receive no mention. Further, it seems unnecessary to insist that uncomplicated cases of measles should be compelled to rest in bed for two weeks after the temperature has become normal. These defects, however, scarcely detract from the merits of the book as a whole, which is clearly and interestingly written, and contains much of considerable value for the practitioner who seeks to keep up to date, for throughout the volume there is a skilful blend of the older well-tried methods with the best modern therapy. Among the numerous remedies advocated there are some little known to practitioners in this country, to whom, too, American nomenclature is sometimes strange. Of these may be mentioned Schlesinger's solution, of the value of which in hopeless cancer cases Professor Barker speaks enthusiastically. It is interesting to note that in several wasting diseases the use of insulin is advised to promote appetite and gain in weight.

This is a book that meets the need of the general practitioner and deserves a wide circulation.

Notes on Books

Dr. O. LEYTON has now published a fifth edition of his little book, *Diagnosis and Treatment of Diabetes Mellitus*,⁵ which first appeared in 1917 and which has been noticed on more than one occasion in these columns. The preface to the new edition ends with the following words: "If the patient will not submit to occasional examination of the blood, all that the physician can hope to do is to retard the progress of the disease. It is not a bad custom to tell the patient who refuses to follow the advice of his physician that it would be wise for him to seek a physician who will give him advice which he can follow."

The plan of *Clinical Contraception*,⁶ by GLADYS M. COX, follows lines that have now become stereotyped in works on birth control. This is a pity, for the author has valuable and original observations to make, and makes them well. As medical officer to two of the largest birth control clinics in this country, she has had a vast experience of imparting birth control instruction and adapting contraceptive appliances to working women; and from the lucidity and orderliness of her exposition in the chapter dealing with occlusive pessaries (as well as in her evaluation of contraceptive devices for normally and abnormally formed women) it is evident that this experience has been assimilated very thoroughly. But in pursuit of an in fact unattainable completeness—an account that should omit nothing which any other writer on the subject may have considered worth mentioning—the author introduces snippets of material (mainly quotations from, and summaries of, original papers) on the chemistry of contraception, hormonal and spermatoxic sterilization, and intrauterine appliances, the clinical significance of which is highly dubious, or at least is seldom sufficiently brought out in the text. These matters are important enough to be discussed as thoroughly as Dr. Cox discusses the practical matters that have come within her very wide experience, or not at all. Wherever the book is concerned strictly with the subject-matter of its title the methods described are those favoured by leading authorities in this country and America.

⁵ *Diagnosis and Treatment of Diabetes Mellitus*. By O. Leyton, M.D., D.Sc., F.R.C.P. Fifth edition. London: Adlard and Son, Ltd. 1934. (Pp. 144. 6s. 6d. net.)

⁶ *Clinical Contraception*. By Gladys M. Cox, M.B., B.S. With an introduction by Lord Horder. London: William Heinemann (Medical Books) Limited. 1933. (Pp. 174. 7s. 6d. net.)

⁴ *Treatment of the Commoner Diseases*. By Lewellys F. Barker, M.D. London: J. B. Lippincott Company. 1934. (Pp. 319. 12s. 6d. net.)

In succession to the three volumes containing the addresses delivered at the fourteenth Concilium Ophthalmologicum at Madrid a year ago, to which reference was made in these columns (1933, i, 1121), five supplementary ones have now been received. The first contains the shorter communications made and the discussions which ensued relative to one of the main subjects considered by the Concilium—namely, retinal detachment. Each is published in the language in which it was delivered, and the tome is fully illustrated with photographs, charts, and diagrams. The second volume includes the special contribution prepared for the congress by Professor Ramón y Cajal, and deals with the histological and physiological problems of the retina. With this is associated a reprint of his monograph on the retina of the vertebrates in view of its great historic importance and the fact of its having been out of print for so long. The author has taken this opportunity to bring the work up to date, and to interpolate in the text illustrative diagrams from his later writings. The third volume comprises the transactions in the course of the congress of the two international organizations concerned respectively with the campaign against trachoma and the prevention of blindness. In the case of the first it was decided that the executive committee would hold a meeting at Budapest in June, 1934, and that there would be a plenary meeting of delegates in 1935 in Holland or Switzerland. In addition to articles on certain scientific aspects of trachoma, there are contributions on the progress being made against the disease in Poland, Spain, and Algeria. In the latter part of this volume the report of the meeting of the International Association for the Prevention of Blindness includes a survey of the more striking advances in different countries, and a classification of the causes of blindness suggested by Professor Marquez. A discussion followed, to which Mr. Bishop Harman and Dr. Ballantyne of Glasgow contributed. These five volumes represent a notable addition to ophthalmological literature, especially taken in conjunction with the three previous ones on tuberculosis of the iris and ciliary body, retinal detachment, and trachoma.

Preparations and Appliances

A RADIUM HOLDER FOR GYNAECOLOGICAL WORK

Dr. SYLVIA D. BRAY, M.B., B.S. (Radium Registrar, Sydney Hospital, Sydney, N.S.W.), writes:

The following is a brief description of a radium colpostat which I have made for applying well-screened radium to the vaginal fornices.

It is made of: (1) two bored rubber corks, such as are used in drop-anaesthetic bottles; (2) tinned copper wire, of such thickness that it is rigid but is easily bent. The wire is

FIG. 1.

FIG. 2.

Colpostat ready for use. Apparatus unprepared.

about 4 to 5 inches long, and is fixed around each cork in a groove; the handle part of the wire is covered by thin rubber tubing before attaching it to the corks. When the radium is *in situ* the corks are covered with rubber dam to cut off the secondary irradiation from the wire.

This apparatus can be contrived in a few minutes, and may be made of any size to fit any vagina and fornices. The wire handle part is especially useful, for by packing gauze over and under this the corks are kept firmly in position.

STERILIZING TRAY FOR RADIUM NEEDLES

Dr. J. MERVYN THOMAS (Cardiff) writes:

As Radium Registrar to the National Radium Centre for Wales, at Cardiff, my attention has frequently been called to the minor but oft-recurring troubles attending the sterilization of radium needles. Such methods now existing involve linen cloths, etc., and only lead to the entanglement of the threads. I therefore suggest the following tray, which fulfils the needs required and may serve a useful purpose in hospitals where radium is available.

It consists of a copper tray about 12 by 6 inches, one end of which is corrugated to hold the radium needles and the other end fitted with a metal handle. About 1½ inches from either end there is a spring clip to fasten the threads securely to a slotted narrow strip. The whole is chromium-plated, and can be placed direct in the sterilizer without fear of (a) bending the needles, (b) entangling the threads.

I am indebted to Mr. Smith, our engineer, for producing this apparatus to my design.

SYRUP MINADEN

Syrup minaden is a "tonic" mixture prepared by the Glaxo Laboratories (56, Osnaburgh Street, N.W.1). It contains vitamins A and D in amounts equivalent to more than an equal volume of cod-liver oil. It also contains a mixture of minerals. Each fluid drachm contains 1/4 grain iron, 2 grains of calcium glycerophosphate, and small quantities of copper and manganese. The syrup has a sweet and pleasant taste, and is particularly suitable for infants and children.

"GLUCOTEST OUTFIT" (B.D.H.)

The British Drug Houses (Graham Street, London, N.1) have introduced a new reagent for the determination of sugar in the urine, and have put up an outfit consisting of three test tubes, a 2 c.cm. and a dropping pipette, together with a 50 c.cm. bottle of "glucotest" solution, test-tube holder, and spirit lamp—price complete, 12s. 6d. The advantage of the solution is that it gives a finer end-point in titration than does the familiar Benedict's solution. A powder is also provided to eliminate "bumping" during boiling and to make the colour change from dark blue to white more definite at the end-point. Two c.cm. of the reagent with 1/2 grain of the powder is transferred into a test tube, urine being added drop by drop from a pipette to the boiling contents. The amount of glucose in the sample is inversely proportional to the number of drops required for the titration, and a table is provided from which the sugar content can be read off in either grains per ounce or percentage. In the case of urine with a high percentage of sugar more accurate results can be obtained by diluting the specimen. The test is easily and quickly performed, and is simple enough to be carried out with success and accuracy by laymen. Parts of the outfit may be purchased separately—for example, a 50 c.cm. bottle of glucotest solution, allowing of twenty-five separate tests, costs 4s. 6d., the pipettes being 1s. 3d. each.

THE NUTRITION QUESTION

AN AGREED REPORT

A notice appeared in the *British Medical Journal* of January 27th (p. 161) from the Secretary to the Ministry of Health saying that a conference had been arranged between physiologists representing the Nutrition Advisory Committee of the Ministry of Health and the Nutrition Committee of the British Medical Association. The conference met on February 6th and 27th, and the following members took part in the proceedings:

Prof. E. P. Cathcart, M.D., D.Sc., F.R.S.	Representing the Minister's Advisory Committee.
Sir F. G. Hopkins, M.B., Sc.D., F.R.C.P., P.R.S.	
Prof. E. Mellanby, M.D., F.R.C.P., F.R.S.	Representing the British Medical Association's Committee.
Prof. S. J. Cowell, M.A., M.B., M.R.C.P.	
G. P. Crowden, M.Sc., M.R.C.S., L.R.C.P.	
Prof. V. H. Mottram, M.A.	
G. C. Anderson, M.D., Medical Secretary, B.M.A.	Joint Secretaries
H. E. Magee, M.B., D.Sc., Ministry of Health.	

At the first meeting Sir Frederick Hopkins was unanimously elected chairman. The conference discussed the differences which appeared to exist between the views of the two committees in regard to the amounts of energy-giving foods and first-class protein appropriate as a basis for suitable diets, and, having come to agreement on these points, issues the following report.

REPORT OF JOINT CONFERENCE

The business before the conference was to consider whether any important differences existed between the recommendations of the Ministry's committee, as stated in its memorandum "The Criticism and Improvement of Diets," and those of the British Medical Association's committee, as outlined in its special Report on Nutrition,¹ and, if so, to determine the significance of such differences.

After examination of the position it became clear to the conference that the divergencies were more a matter of misunderstanding and misinterpretation than of actual fact.

In the first place, it is desirable for a proper understanding of the position that the nature and objectives of the two committees should be made clear.

The Ministry's committee is a permanent advisory body, first appointed in January, 1931, by the then Minister of Health, Mr. Arthur Greenwood. The duties of the committee are to advise the Minister on the practical application of modern advances in knowledge of nutrition. The committee consists of workers with a special knowledge of nutrition, who, as occasion demands, place their scientific knowledge at the disposal of the Minister and his staff to assist him and his department in administrative action. It does not possess any authority, nor does it attempt to give advice on economic matters. In its memorandum "The Criticism and Improvement of Diets" the committee recommended 3,000 calories and 37 grams of first-class protein, or thereabouts, as adequate to supply the needs of the average "man" of the entire population of the country. These recommendations were intended as a rough guide to medical officers of health so as to assist them in placing the nutrition of communities and institutions under their charge on a proper basis. These values, being statistical averages, were meant to be applied to

whole communities, and not to individuals or even to single families. It is in this respect that the purpose of its recommendations differed most markedly from those published by the British Medical Association's committee.

It is necessary also to point out that the responsibility for these and other recommendations made by the Advisory Committee belongs to the members of the committee entirely, and not to the Ministry of Health; and, further, that in the above-quoted memorandum no recommendations of an economic nature were put forward.

The British Medical Association's committee, on the other hand, is not a permanent body, but was a special *ad hoc* committee assembled for a specific purpose—"to determine the minimum weekly expenditure on food-stuffs which must be incurred by families of varying size if health and working capacity are to be maintained, and to construct specimen diets."

The terms of reference thus involved a task of a financial nature, but in order to discharge this the committee had to decide on the food allowances necessary to maintain health and working capacity. In coming to a decision it thought naturally of unemployed men and their families, and bore in mind that many unemployed spend a good deal of their time working on allotments, going to and from labour exchanges and places of employment in search of work, or else in keeping themselves in good physical condition by daily exercise in training centres. And since the food requirements of the individual depend on the amount of physical exercise taken, the committee felt justified in recommending 3,400 calories and 50 grams of first-class protein per "man equivalent" as essential to maintain the health and working capacity of a family of this type. The committee regarded these figures as sufficient to cover a wastage of 10 per cent., but did not suggest that they should be applied to the population as a whole, or even to communities or institutions. It can thus be seen that, whereas the British Medical Association's committee confined its attention to single active families, the Ministry's committee had in view communities of people many of whom lead comparatively inactive lives.

The conference considers it important to emphasize the fact that nutrition and dietetics, dealing as they do with physical and chemical changes inside the body, most of which are imperfectly understood, cannot be considered exact sciences. The calorie is merely a convenient unit for measuring the energy content of food and the energy output of the body. Furthermore, it must be clearly recognized that, owing to individual differences in physique, personal habits, likes and dislikes, and the variations in the degree of muscular effort involved in different occupations, it is not only impossible to define, but also there does not in fact exist, any standard of food requirement which can be rigidly applied to all men alike. If such a standard were defined and universally applied, it would at once be found that, while some individuals were satisfied, others would have either too much or too little. The amount of physical work, housing conditions, clothing, climate, and personal characteristics are factors influencing the need and desire for food which have to be considered when dealing with individual men.

It appears, therefore, that a workable solution of the problem of physiologically desirable dietary standards for individuals can only be found in a sliding scale of calorie needs based on age, individual physique, occupation, and habits. On the other hand, in the case of mass calculations of the total food requirements of the population as a whole, where the question of distribution to individuals or purchasing by single families does not arise, or in the case of communal feeding, the difficulty of the standard ration being suited to the needs of each

¹ *British Medical Journal Supplement*, November 25th, 1933.

individual is largely overcome by the give and take in the food demands of the various individuals making up the community.

It is indeed a fact that, while certain limited classes of men need well above 3,400 calories per day, others need less than 3,000, and therefore the sliding scale of calorie needs now put forward by the conference has been constructed, in the hope that it may provide authorities with a satisfactory working basis on which to determine the needs of individual men and families of varying composition. Such a sliding scale should not, however, be interpreted in too rigid a sense, for the unique nature of each individual's food requirements cannot be too strongly emphasized. The sliding scale adopted by the conference is shown below.

Sliding Scale of Calorie Requirements per Day

Individuals.	Calories gross.
Man: heavy work	3,400-4,000
Man: moderate work	3,000-3,400
Man: light work	2,600-3,000
Woman: active work	2,600-3,000
Woman: housewife	2,600-2,800
Boy: 14-18	3,000-3,400
Girl: 14-18	2,800-3,000
Child: 12-14	2,800-3,000
Child: 10-12	2,300-2,800
Child: 8-10	2,000-2,300
Child: 6-8	1,700-2,000
Child: 3-6	1,400-1,700
Child: 2-3	1,100-1,400
Child: 1-2	900-1,100

The conference also agrees that the all-round-average requirements of the entire population or of large mixed groups of people at the present time is about 3,000 calories per day. This figure can safely be employed for calculations of mass requirements, but in the case of individuals and single families due regard should be paid to the sliding scale detailed above.

Of as great significance to health as calories are the proteins, minerals, and vitamins in the foodstuffs which go to build up the tissues of the body. Because of the special needs associated with the growth and development of new tissue, proteins, minerals, and vitamins are particularly important for children and expectant and nursing mothers.

The general statements recited in regard to standards in respect of calorie requirements apply also to the needs of individuals, families, and communities for protein. Accumulated evidence indicates that the total daily need for protein per man unit probably lies between 80 and 100 grams—that is, from 2½ to 3½ ounces. The precise amount of protein needed by any particular individual depends on physique, occupation, habits, personal tastes, and age, while climate appears also to be a factor of some importance. There is a general consensus of opinion that a certain proportion of the total protein should be in the form of first-class protein—that is, protein of animal origin, such as milk, eggs, cheese, meat, or fish. The desirable proportion of animal protein to total protein has, so far as our knowledge goes, never been exactly determined; but we are convinced from the evidence which is available that the growing child and the expectant and nursing mother require relatively large amounts of first-class protein—much more, indeed, than would be arrived at by simple calculation based on their man-value equivalents.

All recent studies on the nutrition of children have shown that milk is for them a most valuable food. It is indeed the only naturally balanced food we know of, containing as it does in readily available form not only first-class protein (18.7 grams, or 2/3 oz., to the pint), but also minerals, vitamins, carbohydrate, and fat. The conference therefore desires to stress the importance of this highly nutritious food for the child and the nursing

and expectant mother. Both the Ministry's committee and the committee of the British Medical Association were mindful of these facts in regard to the special needs of the child, and both stressed the importance for children of the provision and consumption of milk in adequate quantities.

In the case of the adult the conference is of the opinion that a diet, to be reasonably adequate, should always contain a proportion of protein of animal origin; and that, on the basis of accepted dietaries, which have stood the test of practical experience, this proportion should not be lower than one-third of the total protein consumed, and may perhaps with advantage be increased to one-half.

In applying these recommendations to individuals it must be remembered that in the case of both children and adults the foregoing statements are generalizations, which may well be qualified by individual tastes and variations; and, moreover, it should be pointed out that all proteins of animal origin do not necessarily possess the same nutritional value.

The members of the conference deplore the exaggerated importance which has been attached to the alleged disagreement between the two committees, and wish to avail themselves of this opportunity of stating that there did not exist, nor does there exist now, any fundamental disagreement on matters of scientific fact between the two bodies.

In conclusion, it may be said that it is the earnest hope of the conference that these recommendations will prove of practical value to local authorities and others, and will enable them to place the nutrition of those under their charge, both individually and collectively, on a sound basis, in the interests of the health, fitness, and well-being of the nation.

THE MINISTRY'S CIRCULAR

The above report is being issued to county councils and sanitary authorities in England and Wales by the Ministry of Health, together with the following letter (Circular 1406), signed by Sir Arthur Robinson, Secretary of the Ministry:

I am directed by the Minister of Health to refer to Circular 1370 of January 4th last, relative to the report made by a committee appointed by the British Medical Association "to determine the minimum weekly expenditure on foodstuffs which must be incurred by families of varying size if health and working capacity are to be maintained, and to construct specimen diets."

Reference was made in the circular to certain respects in which the conclusions of this committee differed from the principles enunciated by the Minister's Advisory Committee on Nutrition in their memorandum on the Criticism and Improvement of Diets, and it was subsequently arranged that three physiologists representing the Advisory Committee should confer with three physiologists representing the British Medical Association Committee in regard to the differences which appeared to exist between the two committees on the question of the amount of calories and first-class protein appropriate as a basis for suitable diets.

The Minister has now been furnished with the report of this conference, and he directs me to forward a copy of the report for the information of the local authority. Copies of the report and of this circular are also being sent to the medical officer of health, and further copies may be obtained from H.M. Stationery Office.

British Medical Journal

SATURDAY, MAY 19th, 1934

THE PATHOLOGIST IN MEDICINE

The place of the laboratory in the modern world forms the subject of a well-written little book by Dr. D. Stark Murray,¹ who is one of the assistant pathologists under the London County Council. Though the book is presumably intended for the lay public, it can hardly fail to prove of interest to medical men who are unaware of the enormous strides taken by laboratory workers of recent years. Dr. Murray does not confine himself to the pathological laboratory; his survey extends over the whole field of academic, routine, and industrial scientific endeavour, and it is for this reason that his tale is of such general interest. But it is mainly with the pathological laboratory—using this term to include morbid histology, experimental pathology, bacteriology, and biochemistry—that his reflections are concerned. How great a change has come over pathology during the last twenty years it is difficult to realize. Before the war the pathologist was too often a poorly paid, rather secretive worker, who was housed in what was often no better than a cubby-hole, whose main duty was to act as a servant of the clinician, and who, if he did engage in research, made practically all his observations himself. Now he is much better paid, he is coming far more into the open, he has in many instances entirely detached himself from clinical work, he is housed in excellently designed and well-equipped laboratories, and with the help of often numerous assistants, who do the majority of the technical work, he is able to investigate fundamental problems concerning the pathogenesis of disease. Whereas before the war money for research was scanty and scholarships were few, there are now so many sources of income which can be tapped and so many scholarships and fellowships available that great new institutes have arisen, employing scores of workers and spending several thousand pounds each year on research, which is coming more and more to rely on co-operative investigation and team work.

With this greatly increased importance of the pathologist, it is not surprising that Dr. Murray raises the question of his financial remuneration. His salary is not only diminutive compared with the income of a successful clinician, but it is much less than his abilities would win for him in commerce. It is said, of course, that the laboratory worker derives such satisfaction from the results of his work that he is not justified in expecting any great financial reward. This is true up to a point. It was true, for instance, before the war, of the don at one of the older universities,

who led a peaceful life, free from worry and intrusion, whose work alternated pleasantly with play, and whose privilege it was to explore the delights of a well-stocked cellar. But this picture is not true now. In the larger and more important centres of teaching and research the senior pathologists are burdened with an amount of work and responsibility that is often far more than that of administrative officials who receive a greater income and who do not suffer from that continuous urge to do research from which the real scientist is never free. The life of such a pathologist is no longer peaceful; he is no longer left to work quietly in his own laboratory. Besides having to take his share in the teaching or routine work of the institute, he is expected to serve on numerous committees, to place his expert knowledge free of charge at the disposal of Government Departments, to write reports on special subjects, to apply to different outside bodies for grants and scholarships for perhaps half a dozen workers under his care, to supervise the whole of the research activities of his department, to carry on a correspondence with persons in other countries who are working along similar lines to his own, to inform himself of the main inquiries being conducted in other institutes, to attend the usual pathological meetings, to receive visitors and answer telephone calls at both convenient and inconvenient hours, and all the time to keep himself abreast of a scientific literature which every year becomes more and more overwhelming. Such a life may be interesting, but it is one full of responsibility and care, and one that demands adequate remuneration.

The rapid change that has come over pathology raises a problem of increasing importance. How is the experienced pathologist to find time for individual thought and research work? With very few exceptions no outstanding piece of work is done by a young man working on his own. The old days, when qualitative observations of real value could be made by workers coming to pathology afresh, or more frequently by half-time workers, are gone, and it takes years of observation, reading, and experience to gain a sufficient knowledge of the field to judge what lines of investigation are likely to be most fruitful. Just at the time, let us say 40 years of age, when the pathologist has gained this knowledge, when he has learnt how to make an experiment, and when, most important of all, he has acquired the ability to define his problem, he is taken away by a multitude of administrative and consultative duties, and prevented from thinking about or carrying out research work with his own hands—research work of a type which has often to be done by the individual before it can be handed over for extension or completion to skilled assistants. This state of things, which has long been deplored in the medical services of the Army and Navy, is now becoming established in civil life, and is being viewed with increasing dismay by workers who are finding themselves in a position very different from that to which they had looked forward on first taking up a

¹ *The Laboratory: Its Place in the Modern World.* By D. Stark Murray, B.Sc., M.B., Ch.B. London: The Fenland Press. 1934. (Paper, 2s.; cloth, 3s.)

scientific career. What the solution of this problem is no one can say. Possibly the establishment of the Leverhulme Fellowships to enable senior workers to take a year or so off from their ordinary duties in order to concentrate on particular problems may be a step in the right direction. In any case the position is serious enough to demand the consideration of those who are interested in the future of medical science.

GAS WARFARE

A short time ago the British public heard reassuring words about the harmlessness of gas warfare, and it was even suggested that an aerial gas attack on a city need only be the occasion for a quiet rest in a warm bath. It is probable that these comforting views were accepted most readily by those who had not had first-hand experience of the effects of poison gas, and, moreover, a survey of foreign medical literature suggests that the Continental outlook on this subject is very different. Interesting articles have been published in the last few years dealing with the medical problems likely to arise from aerial gas attacks on civilian populations,¹ and a fairly exhaustive summary of the actions of certain war gases has just appeared in the current number of *Tabulae Biologicae Periodicae*.² This latter account is, of course, incomplete, because all the newest and most potent gases are secret. In the introduction to the article it is, however, pointed out that reports regarding new gases of fantastic activity ought to be received with the greatest scepticism. This suggestion gains confirmation from the published data which indicate that Lewisite (monophenyldichlorarsine) has a toxicity not very much greater than that of mustard gas, though highly sensational reports were current at one time about the activity of the former compound. It is interesting to note, however, that one table in this article contains a description of no fewer than sixty-two poison gases, the majority being complex organic compounds containing halogens or arsenic. Since the toxic actions of all of them have been studied most carefully it is clear that a great deal of research has been prosecuted on this subject.

The term "poison gas" is rather a misnomer, because a large number of the most effective compounds do not form true gases, but produce clouds either of droplets or of solid particles. Poison gases have been classified as follows: (1) "Green cross," which are true gases—for example, chlorine and phosgene. (2) "Yellow cross," most of which are heavy fluids forming clouds of droplets—for example, mustard gas and Lewisite. (3) "Blue cross," most of which are solids forming clouds of particles—for example, Adamsite (diphenylamine chlorarsine). The green cross gases attack the lungs; the yellow cross are vesicants and also produce lung injuries if inhaled; while the blue cross are the tear and sneezing gases, which, if once inhaled,

render the wearing of a gas mask impossible. It is a curious fact that it is more difficult to produce gas masks which protect completely against the toxic dusts of the blue cross series than against the true gases and the liquids. The article under discussion contains details regarding gas filters, and gives data for calculating the efficacy of various types of charcoal, etc. In this connexion it is of interest to note that some of the modern gas masks made in Germany are constructed with a series of seven different filters. This indicates how complex a mask has to be if it is to prove effective against all likely toxic agents. In a series of tables showing the relative toxicity of poison gases we find no record of any agent with a toxicity greatly superior to mustard gas; but unfortunately this does not prove that no such compound is known, for if a much more diabolical agent were discovered it would be kept secret.

The most reassuring table in the article is one giving a summary of the effects of gas in the world war of 1914-18. The percentage of gas casualties that died varied from 4 to 1.7 in the different armies; this is a 'surprisingly low' mortality. Massed figures which include all armies show a total of 35 million casualties with 10 million deaths, but out of the one million gas casualties there were only about 30,000 deaths, indicating that gas was much less lethal than other weapons of war. On the other hand, we have to remember that these figures record the effects of gas on soldiers scattered thinly over open country, fully equipped with gas masks and well trained in their use, and results obtained under such conditions do not indicate the probable effect of gas attack upon the population of a city. The increasing attention which has been paid to poison gas in recent years is certainly disquieting.

PROSPECTS IN THE R.A.M.C.

For some years all has not been well with the medical branches of the Defence Services. Of the causes of dissatisfaction, inadequacy of pay and pension and restriction of professional opportunity have been the most important, and reduction in the number of men taking up this career was an inevitable consequence. In May, 1931, a Committee, under the chairmanship of Sir Warren Fisher, was set up by the Prime Minister to investigate the causes of the shortage of officers and nurses in the medical and dental branches of the Defence Services, and to recommend by what means the situation could be remedied. This committee imposed upon itself a condition that its recommendations should not involve increase in total expenditure, and its conclusions must be viewed in the light of that limitation. The British Medical Association gave exhaustive evidence before the committee, and after considerable delay the final report, the "Warren Fisher Report," eventually appeared in July, 1933. The Naval and Military Committee of the Association, with the help of special subcommittees, carefully examined the report from all angles and submitted memorandums thereon to the respective departments. To these the departments have replied in considerable detail, and the Royal Warrant relating to the

¹ *Deut. med. Woch.*, 1932, lviii, 1629; *Forsch. d. Medizin*, 1933, li, 168.

² *Tabulae Biologicae Periodicae*, Band III, Nos. 2 and 3. Berlin: W. Junk, 1933. (11.55: subscription price, M.48.)

R.A.M.C. was published on April 27th, 1934,¹ and considered by the Naval and Military Committee on May 15th.

In effect, the Royal Warrant indicates that the Army Council has adopted the suggestions of the Warren Fisher Committee. All entrants will receive short-service commissions, and at the end of five years an officer will have the choice of retiring with a gratuity of £1,000 or applying for a permanent commission. As a result of substantial upgrading, an officer in the permanent service will spend a larger part of his career in the higher ranks than formerly. Assuming that the officer joins at 25 and is granted a permanent commission, it is guaranteed that he will be a captain at 26 and a major at 35, instead of at 28½ and 37 as at present. Pay in the various ranks remains unchanged, but promotion is accelerated. Promotion to lieutenant-colonel and colonel will be by selection, and it is estimated that it will occur, on the average, after seventeen and twenty-five years respectively. This is to be achieved by a careful control of the permanent entry. Further, the career of the average officer will be lengthened and will normally extend to the age of 57. How has the pay—and in consequence the pension—of the average officer been improved? Assume that the officer joins the Service at the age of 25 and that he is accepted for permanent service:

Age	Former Rate	New Rate
25	£ 356—Lieutenant	£ 356—Lieutenant
26	356—Lieutenant	438—Captain
35	529—Captain	608—Major
42	690—Major	934—Lieut.-Colonel
48	934—Lieut.-Colonel	1,016—Lieut.-Colonel
50	1,016—Lieut.-Colonel	1,138—Colonel

Short service is the first essential of this scheme, because there must be control of permanent entry if the promotion by selection is to take place at the estimated time. Reduction of establishment is a second essential, and civil practitioners will be employed to the extent that is necessary. It is hoped that one consequence of reduction of establishment will be the concentration of medical officers on actual professional work and a corresponding reduction in non-medical administrative duties. An increase in the number of specialist posts carrying specialist emoluments is another recommendation of the Warren Fisher Committee directed to this end; of officers on the permanent establishment, one-third will be receiving specialist emoluments. A question of highest importance is the degree to which the proposals are to be applied to existing officers and particularly to the large number of majors awaiting promotion to lieutenant-colonel. The problem of the wave of majors awaiting promotion to lieutenant-colonels now as a result of the abnormal 1915-16 entry is one of the greatest difficulty. How many of them will be upgraded to enable them, at least, to retire on lieutenant-colonels' pensions? It is understood that the intention of the War Office is to apply the upgrading proposals to existing officers in the shortest possible time. We observe that in the *London Gazette* of May 8th it is announced that forty-five majors are

promoted from May 1st to lieutenant-colonels and twenty-one lieutenant-colonels to colonels. We are assured that almost every existing major will reach the rank of lieutenant-colonel, enabling him to retire on the pension of lieutenant-colonel.

These were the changes that the Naval and Military Committee considered at its meeting on May 15th. The changes in terms and conditions of service have not been made in the way the Association hoped—a state of affairs not altogether dissociated from the financial limitation which the Warren Fisher Committee imposed upon itself. Proposals were made by the Association which the Warren Fisher Committee and the War Office have not found it possible to accept. We regret that this is the case. Nevertheless, a careful examination of the changes has convinced the Naval and Military Committee that the reconstruction of the Royal Army Medical Corps on the lines of the Warren Fisher Report, if faithfully and consistently carried out, will do a great deal to make the corps a more attractive career. This is the view that the committee is recommending to the Council. It is a bold experiment, and we think that the R.A.M.C. is worthy of the consideration of the young medical man seeking a career in which professional work, travel, and service life are possible at good pay with assured prospects of promotion and pensionable retirement.

THE ROYAL SOCIETY CONVERSAZIONE

The Royal Society held a conversazione at Burlington House on the evening of May 9th, when the President, Sir F. Gowland Hopkins, received the distinguished guests who had come to catch a glimpse of the multifarious activities of the world of science. In its choice of exhibits the Royal Society is refreshingly latitudinarian, for between a demonstration of a fractional-seconds chronograph and one of the phthalocyanines was a table of photographs illustrating the ravages effected by the bed bug in the slums. The bed bug itself, safely corked, was also shown in different phases of its career, and in various states of hunger and repletion. This exhibit included a photograph of a fumigating machine which can clear a house of bugs within eight hours. Of particular interest to readers of last week's *Journal* was a demonstration by Sir Henry Dale, Dr. W. Feldberg, and Dr. A. Vartiainen of physiological tests for the detection of acetylcholine. Captain S. R. Douglas, Mr. P. P. Laidlaw, and Professor W. Levinthal arranged a number of stained specimens of the virus of psittacosis, which could be seen as a minute coccoid micro-organism, and inclusion bodies in a section of the nasal mucous membrane of a ferret with dog distemper. A microscope for ultra-violet microscopy was exhibited by Mr. J. E. Barnard. What is now known as the Bragg pulsator narrowly escaped not being shown at the conversazione, for the model to be demonstrated was in practical use elsewhere until the early part of the evening. At Sir William Bragg's request the apparatus was designed by Mr. R. W. Paul, M.I.E.E. It consists of an inflatable air-bag, or belt, which encircles the chest (the bag has a non-extensible outer skin), a pulsator which rhythmically inflates the bag, and a controller which governs the speed of the pulsator.

¹ *British Medical Journal*, May 5th, 1934, p. 830.

The apparatus can be worked off the water supply or by electricity. It is silent and automatic in operation, is easily transportable, and seems admirably to fulfil its function of carrying on artificial respiration for as long as this is needed. Interesting experiments in histochemistry were illustrated by specimens set up by workers from the Strangeways Research Laboratory at Cambridge: Mr. C. H. Waddington and Drs. J. and D. M. Needham have found that the activity of the organization centre of the amphibian egg, which controls the formation of the axial embryonic organs, is due to an ether-soluble substance. These workers have also found that the injection of sterols (such as cholesterol, calciferol, oestrol) into the developing embryo causes proliferation, without differentiation, of the ectoderm; similar effects, grading into true inductions (for example, of a structure resembling a neural tube), were also obtained with the carcinogenic hydrocarbon 1.2.5.6. dibenzanthracene. Among other exhibits were microscope slides showing sericite fibres in silicotic lungs and in rocks and substances giving rise to dangerous dust, by Dr. W. R. Jones; a Metropolitan-Vickers portable noise-measuring apparatus; evolution in the budgerigar under domestication, by Professor R. C. Punnett; and the earliest known dated optical instrument in the world, a telescope of 1646, shown by Mr. George H. Gabb.

CENTENARY OF THE LIVERPOOL MEDICAL SCHOOL

This centenary was celebrated on Friday, May 11th, by a ceremony in which the University conferred a number of honorary degrees. The Liverpool School has in the past enjoyed much richness of personality, and with possession of the necessary facilities for study there is good reason to believe it will continue to develop as a worthy seat of learning. At the graduation function nearly a score of delegates from British and Irish universities were present, as well as representatives of national medical bodies, and the mayors of eight neighbouring boroughs. The Chancellor of the University—the Earl of Derby—was unable to attend, and he was represented by Pro-Chancellor Lord Leverhulme. Among others present were: Sir Norman Walker (President, General Medical Council), Sir H. J. Waring (President, Royal College of Surgeons of England), Dr. H. Morley Fletcher (Royal College of Physicians of London), Sir Ewen Maclean (British College of Obstetricians and Gynaecologists), and Dr. J. O. Wakelin Barratt (Master of the Society of Apothecaries). In his address the Vice-Chancellor—Dr. H. J. W. Hetherington—expressed, on behalf of the University, their pride in the shining record of the medical school and faculty, and continued: "In the romantic record of the last century this school has borne its share—in all parts of the world, and in every phase of medicine, of surgery, and of the sciences of which these arts have increasingly availed themselves. Its work has been the product not only of individuals of insight, and even of genius, but still more of the continuous and friendly co-operation of men who have given themselves devotedly to their task. We do well to recall to ourselves the heritage which has been given to us, and in that act to think of this day as but the opening of another epoch in our history." An

address on the Liverpool School of Medicine was given by Professor John Hay, who suggested the foundation of a chair in clinical science. The professor, he said, should be a clinician with special training in the elucidation of scientific problems; his activities would be complementary to, and independent of, those of the professor of medicine. Honorary degrees were then conferred on the following distinguished persons: Professor Henry R. Dean, Sir Thomas Lewis, Mrs. May Mellanby, Mr. Wilfred Trotter, F.R.C.S., Emeritus Professor Blair-Bell, Emeritus Professor Henry Briggs, Dr. Herbert R. Hurter, Dr. W. S. Paget-Tomlinson, and Emeritus Professor C. H. Réilly.

CLINICAL TEACHING IN THE U.S.A.

In the Hospital Number of the *Journal of the American Medical Association*, under date March 31st, are three papers dealing more or less directly with medical education: "The Restoration of the General Practitioner," by Dr. Dean Lewis; "The Out-Patient Clinic," by Dr. J. H. J. Upham; and "The Importance of Introducing Psychiatry into the General Internship," by Dr. Franklin G. Ebaugh. The chief impression left after reading these articles is perhaps a pronounced sense that both situation and nomenclature are different in the United States from those which obtain in this country. Happily here in Great Britain there is no need to "restore" the general practitioner: he has never lost his position as the mainstay of the profession, or in the first line of defence of the health of the nation. The out-patient department of the hospitals, though clearly in many cases in need of reform, can with relative ease be dealt with on lines already broadly marked out and largely agreed upon. Medical psychology and psychotherapy (for, in American, the term "psychiatry" appears to connote these) are already recognized, or at least seem on the point of recognition, as essential parts of the teaching of every medical practitioner. In America it seems that until lately "everything up to the eyebrows belonged to the consideration of the physician, while all above them was relegated to the cleric and philosopher." Dr. Dean Lewis differs widely in his ideas about disease from Dr. Ebaugh. He says: "A deep knowledge of pathology is the foundation stone of diagnostic ability," and quotes with approval the statement: "The observation of function is of little value if it is divorced from the alteration of structure. Our studies of function serve chiefly to allow us to decide accurately the character and extent of structural lesions." Dr. Ebaugh emphasizes that the practitioner "becomes cognizant after not too many weeks that he is unable to find 'pathology' to account for all symptoms and complaints presented. Chest thumping fails to reveal the mysteries surrounding the strange case. Unless he is willing to consider the individual in his entirety, to evaluate his life situations and emotional responses, he is of little service to his patient." Dr. Upham makes one important point very well. "Practitioners of medicine," he says, "have not a vested right in patients, but they do have a definite and necessary place in the social and economic scheme of life and a moral right to expect returns for many years of preparation for practice.

They expect the competition of other practitioners, and this has a wholesome effect in keeping up and improving the quality of service; but the giving of medical service by free clinics to those able to pay is unfair competition, and every effort should be made to avoid it."

A DIABETIC CLINIC

The diabetic clinic at King's College Hospital, London, under Dr. R. D. Lawrence, which has been functioning for several years, and has built up a reputation and a clientele far beyond the confines of Denmark Hill, has lately moved into enlarged quarters in the hospital and is rejoicing in new equipment. The clinic was to have been opened by Mr. H. G. Wells on May 11th, but he was called away to the United States, and there was no formal opening ceremony, though a number of visitors were received by Dr. Lawrence and inspected the rooms. It would have been appropriate if Mr. Wells had been able to be present, as it was in response to an appeal of his that last year Mr. W. Chapman of Capetown supplied funds for the refurnishing. The clinic, which consists of a series of rooms chiefly for consultation and examination, is on the ground floor of the hospital, but is still separated by a considerable distance from the kitchen where the meals for the diabetics are prepared and served. A large, specially constructed trolley for the conveyance of food is the gift of a number of ladies of the neighbourhood. A feature of the kitchen is the crockery cupboard, which, with its contents and other cookery utensils and a refrigerator, is the gift of the diabetic patients themselves, who also attend to all replacements. Under the sister in charge of the clinic the patients receive instruction in dieting and in insulin administration. The new department includes a cheerful waiting room for out-patients, screened cubicles for investigation, with equipment for the necessary ophthalmic and other examinations, and a consulting room, which can be curtained off to make three, for the medical staff. There is also a laboratory bench for blood sugar and other determinations. The hospital has from 100 to 150 in-patients in a year with diabetes, and the number of out-patient attendances, which was 1,746 in 1930, 2,069 in 1931, and 2,472 in 1932, rose to 3,324 in 1933, and the curve is still ascending.

HUNTINGTON'S CHOREA

An extremely interesting account¹ has recently been given of Dr. George Huntington of Easthampton, Long Island, New York, who in 1872 published the account of the chronic hereditary disease with mental deterioration which bears his name. He was a general practitioner, born on April 9th, 1850, the day after Professor W. H. Welch, with whom there is another rather remote association; for the Huntington family came from Norwich in 1633, and two of them in 1660 laid the foundations of the present city of Norwich, Connecticut, which is at the opposite end of

that State to Norfolk, where Professor Welch was born on April 8th, 1850. George Huntington in 1872, when on a visit to Pomeroy, Ohio, read a paper on the ordinary chorea of children, at the end of which he added the account of a disease which, as far as he knew, existed almost exclusively in the east end of Long Island, where ordinary chorea was extremely rare. It was confined to a few families who regarded it with horror, and were reluctant to mention it, and then spoke of "that disorder" or the "megrims." Its hereditary character was continuous, and if one generation escaped their offspring were immune. It was further prone to cause insanity and induce suicide; and did not begin, at least as a grave affection, until adult life. Huntington, who was then a very young practitioner, later dutifully pointed out that his description of the disease was based on the observations and information handed to him by his father and grandfather, who had practised in Easthampton since 1797: The disease had not entirely escaped previous notice, for it was mentioned in 1842 by C. O. Waters, and in 1863 Irving W. Lyon wrote on chronic hereditary chorea; but Huntington's was the most graphic and accurate account. To refer to printers' errors is invidious, but this otherwise admirable article by Dr. C. S. Stevenson contains a transposition, it would almost appear of diabolical ingenuity, which to the rapid reader might give Dr. George Huntington, who died in 1916 aged 66, the credit of having been engaged to be married for the record period of ninety-two years.

We regret to announce the death of Mr. Frank Kidd, M.Ch., F.R.C.S., formerly surgeon and surgeon in charge of the genito-urinary department at the London Hospital.

We regret to announce the death of Sir A. Jarvie Hood, M.B., C.M., consulting physician to the Sydney Hospital, who had been a member of the New South Wales Branch of the British Medical Association for nearly fifty years.

The next session of the General Medical Council will open on Tuesday, May 29th, at 2 p.m., when the President, Sir Norman Walker, M.D., will take the chair and give an address. The Council will continue to sit from day to day until the termination of its business.

A complimentary dinner to Mr. R. H. Burne, M.A., F.R.S., was held at the Langham Hotel on May 10th, on the occasion of his retirement from the Physiological Curatorship of the Museum of the Royal College of Surgeons of England after forty-two years in the service of the College. The chair was taken by Sir Holburt Waring, the President of the College, and among those present were: Sir Cuthbert Wallace, Sir Arthur Keith, Sir Arthur Smith Woodward, Sir Peter Chalmers Mitchell, Dr. Tate Regan, Sir Charles Ballance, Professor F. Barclay-Smith, Professor William Wright, Sir Buckston Browne, Professor E. S. Goodrich, and Mr. C. Forster-Cooper. Mr. Burne's health was proposed by Sir Holburt Waring, supported by Sir Arthur Keith and Sir Peter Chalmers Mitchell.

THE PROFESSIONAL MIND

MAUDSLEY LECTURE BY LORD MACMILLAN

The fifteenth Maudsley Lecture, under the auspices of the Royal Medico-Psychological Association, was delivered by the Right Hon. Lord MACMILLAN, M.A., LL.D., Lord of Appeal in Ordinary, on May 17th, at Manson House, Portland Place.

After some prefatory remarks on the admonition which he said had been given him that he must on this occasion deliver a popular address Lord Macmillan asked his audience to consider certain phenomena which, while they fell within a special province of psychiatrists and psychologists, were at the same time matter of common observation and interest—namely, the phenomena exhibited by various types of the professional mind in its daily working. The choice and practice of a profession had a decisive and pervasive influence on a man's whole mental outlook. The first question asked about a new acquaintance was, "What does he do?" and the answer afforded the first clue to the kind of man he was, for, wide as were the individual differences among the members of a profession, there were always common elements shared by all belonging to it. Their habits were controlled; their thoughts canalized, their prejudices formed, by the profession they practised. Even their place of residence might be dictated by their vocation, as witness the Temple for lawyers, and Harley Street for medical men.

Dr. Henry Maudsley, after whom the lecture was founded, in discussing the larger topic of the inculcation of morality, had described the process as one of moral manufacture, and had pointed out that the whole purpose of education in morals was to produce a nature in which moral action should have become automatic. Each moral act by the law of nervous action rendered the next more easy, and so a man's nature was gradually modified. It was by some such means, together with imitation, that the process of professional training and experience gradually moulded the mind and character until the man's reactions became largely instinctive. Thus it was said, generally in a disparaging way, of lawyers, "Oh! He is a lawyer; you know how lawyers always look at things."

PROFESSIONAL ORGANIZATION

From the earliest times the practitioners of a particular art had shown a tendency to draw away from the rest of the community and to constitute themselves a separate class with their own ceremonial rites and shibboleths. The widest of all caste cleavages in former days, and still a wide one, was that between the clergy and laity. Within the ranks of the laity in turn many associations grew up of men united by a common calling. Lines of demarcation were much more rigidly drawn in former times, and the resulting mutual exclusiveness produced much more distinctive types of persons. Nowadays the barriers were broken down, and men of all careers mixed with each other—certainly a more excellent way of living. Nevertheless, there still remained certain typical attributes engendered by the life-long pursuit of a particular calling, and lending colour and interest to social life.

COMPETING INTERESTS

While it might be claimed, Lord Macmillan continued, that devotion to a common calling tended to create a sense of professional brotherhood, and thus widened and liberalized the minds of its practitioners, there was, on the other side of the account, a mental tendency resulting from immersion in a profession which was not so meritorious. This was the tendency to resist all changes. Those who, after much time and labour, had acquired facility in the practice of a system were naturally disinclined to scrap what they had found to work well enough. They were reluctant to make the effort of examining and adopting new ideas which might be subversive, and the beaten path

was so much easier to tread. As an illustration he briefly glanced at the hostility often shown towards the discoveries of the great pioneers in medicine, but in the gathering he was addressing he thought it more discreet as well as courteous to refer to the inveterate conservatism of his own profession, that of the law; or again, he might instance the Civil Service. The truth was that no profession or calling was immune from this tendency. The prophet had always been greeted with a volley of stones, for, to quote Professor Whitehead, "Routine is the god of every social system." There was a good side as well as a bad one to this instinct. It was not all obscurantism. Without the stability of routine the social fabric would disintegrate. Resistance to innovation was part of the protective armour of civilization. The same Scriptures which lamented the stoning of the prophets bade those who followed them prove all things and hold fast that which was good.

Another charge which, so far as it held good, must be placed to the debit side of the reckoning, was the proneness of the professional mind to put the interests of the craft before those of the community. Changes were often advocated in the general interest which were inimical to the interests of those engaged in a particular calling, and these were apt to resist the changes, not on their merits, but for purely selfish reasons. Examples would occur to his audience, but he thought it better again to be discreet. He wondered what Adam Smith, who was very critical of professional and trading corporations in his time, would have thought of the innumerable congresses and conferences which in these days were constantly being held by every trade, calling, and profession. There was more lip service nowadays to lofty social motives, but the pursuit of selfish aims under the guise of public good was not an unknown phenomenon.

THE LIMITATIONS OF THE EXPERT

In these days an increasing resort was made in all departments of life to the particular type of professional man known as the expert. In medicine the specialist had long been a familiar figure, but there were specialists now in every branch of human affairs, the reason being that the field of knowledge had become so vast that no individual could hope to be master of more than a corner of it. When a public problem arose in any province of administration the demand always was for the expert to be consulted, if not put in charge. The results were not always happy. The expert mind as a species of the genus professional mind was apt to have failings as well as excellencies. The attainment of a highly specialized knowledge of one isolated subject tended to create a certain arrogance of assurance. It was not unnatural to assume that if one knew *more* about a subject than anyone else one knew it *better* than anyone else, but he doubted whether that was necessarily so. It might be so if human life and knowledge were divided into watertight compartments, but no one factor in the social organism could be isolated. The result was that the conclusions of the specialist had often to be corrected and modified when brought into relation with wider considerations. The constitutional tendency of experts to differ, so unjustly associated in the proverb with the medical profession only, had also to be considered. The faith of the public in political economists had been rudely shaken by the discordant advice they had tendered since the war. This proneness of experts to differ was easily explicable. Even the most arrogant expert would not lay claim to complete knowledge of his subject: he had probably devoted himself to one aspect of it to the exclusion of others, and having formed certain opinions from what was, after all, only partial knowledge, he developed a parental affection for them which became emotional rather than scientific.

On the other hand, the value of specialized knowledge was incontestable, being the product of intensive research and experience quite beyond the range of the ordinary practitioner. One of the most interesting problems of the day was how best to utilize the expert in the public interest. Lord Macmillan here digressed to speak of the

various methods in which the expert was utilized in the law courts, and put forward the strong view, in discussing the expert witness, that no scientific man ought ever to become the partisan of a side; he might be the partisan of an opinion of his own science, if he honestly entertained it, but he ought never to accept a retainer to advocate in evidence a particular view merely because that was the view which it was in the interests of the party who had retained him to maintain. To do so was to prostitute science and to practise a fraud on the administration of justice.

A less perilous sphere for the exercise of the expert mind in the administration of justice was to be found in the utilization of the expert as a referee, as, for example, under the Workmen's Compensation Act. The medical referee was exempt from the temptations of the witness-box, and had to exercise the functions not of a partisan but of a skilled adjudicator. It was a highly responsible part to play, but he had no doubt that the duty was faithfully and conscientiously performed. Another method in which the law invoked the aid of the expert professional mind was by employing the expert as an assessor. On the whole the lecturer was disposed to think that it was in some form of consultative capacity that the abilities of the expert mind were best utilized in the public service. The faculty of practical judgement was not always to be found in conjunction with scientific learning. The art of judgement was itself an art. The judge, the statesman, and the business man might often be better able than the expert to reach a wise solution of a practical problem, even though it did involve technical matters, but it was essential that the requisite technical assistance should be at his disposal.

THE LEGAL MIND

Lord Macmillan next passed to consider some of the mental phenomena exhibited by the practitioners of the three learned professions—the Church, the Law, and Medicine. Sir Walter Scott uttered the pregnant aphorism that "the clergy live by our sins, the medical faculty by our diseases, and the law gentry by our misfortunes." It was odd to think that the main object of the clergyman, the doctor, and the lawyer was to combat in each case the very thing which was the cause of his existence. Nevertheless, the clergyman was not always in the confessional, the doctor by the bedside, or the lawyer in the courts.

Speaking of the legal mind, the professional type which throughout the ages had been most consistently the subject of deprecatory comment, he said that the advocate was supposed to be perpetually engaged in distorting the truth in his efforts to make the worse appear the better reason. Speaking from a long experience, he could only say that the conception of the advocate as a kind of artful dodger who made his living by stupefying his conscience was utterly remote from the truth. He would even go so far as to say that the lawyer encountered no more problems of moral conduct in his daily professional life than did the practitioners of any other art or business; there was no profession which had a higher, a better recognized, or a more rigidly enforced standard of honour. But the great bulk of the legal work of the country was administrative and non-contentious, requiring no perverse intellectual subtlety, but just the ordinary workaday virtues of industry and honesty. At the same time he was not blind to elements of truth in the popular caricature. The profession undoubtedly tended to foster certain intellectual habits, which, when they became exaggerated, were not admirable. The business of the lawyer was pre-eminently with words, not with things, and a pre-occupation with words ("Wise men's counters," as Hobbes said, "but the money of fools") had its dangers. There was a danger even in logic in human affairs. The practical problems of humanity were not solved by syllogisms or by neatly framed codes. There was a proneness in the legal mind to prefer formulas to facts, and to place too much reliance on the power of words.

Another defect commonly attributed to the legal mind was that it was unduly critical. The critical habit was useful in its proper place, but often handicapped the lawyer in dealing with constructive proposals where success could be attained only by disregarding risks. Therefore lawyers were not temperamentally well fitted for leadership either in politics or business, where an adventurous spirit was essential. In the State and in society the most useful function of the legal mind lay in the orderly and just regulation of human relations.

THE OUTLOOK OF THE PHYSICIAN

Turning to the profession of medicine, Lord Macmillan said that it seemed to him that the outlook of the physician upon life must necessarily be widely different from that of the lawyer, his service to humanity being of an altogether different order. Sir Wilfred Grenfell had said that in Labrador the Eskimos called him by a name which meant "the man that has to do with pain." The effect on the mind of constant contact with human suffering could not but be profound. The relation between a patient and his medical adviser had an intimacy which did not subsist between a client and his legal adviser, and it was a relation which made a call upon the emotions as well as upon the intellect. In study and research the medical man was a man of science, and might be expected to exhibit the mental qualities of accurate observation and induction, but in the region of professional practice calls were made upon him of a very special nature. There was no exact science of therapeutics, and its practice must be largely empirical. Diagnosis required not only knowledge but reasoning power, and often imagination as well. Personality counted for much, and the mere presence of a trusted medical adviser might itself be therapeutic. The demand thus made upon his physical, mental, and emotional resources created a special type of character, exemplified in the highest degree in those who had to minister to minds diseased. Moreover, the exacting nature of the doctor's work and its irregularities tended to cut him off to some extent from the ordinary social life and public work.

IS THERE A DEFINITE MEDICAL TYPE?

Could it be said that there was a distinct medical type of professional mind? The lecturer thought there was, but it was not easy to put into words. The role which the doctor was required to play must react on his mental and moral make-up. "I do not believe that his constant contact with suffering renders him callous, but he must acquire a certain calmness in the presence of the emergencies and tragedies of life which is apt to be mistaken for unconcern. His natural sympathies must be under control if he is to perform his work adequately. The very confidence which is reposed in him and the immunity from publicity which he enjoys may tend to make him professionally oracular. The traditions of spells and incantations dies hard, and prescriptions are still made up in hieroglyphics. On the other hand, the unselfishness and devotion to duty which are the very hall-mark of the profession far outweigh any of the foibles which may be laid to its charge. It is perhaps in the medical man that the professional mind finds its finest sphere. At any rate I envy the physician the epithet which is peculiarly his own, and which gratitude and affection have bestowed on him, the epithet 'beloved.' I have never heard of a beloved barrister or a beloved solicitor."

The Prussian Minister of the Interior has revoked his decree of December 20th, 1933, described in the *Journal* of March 24th (p. 565), in so far as to allow anti-vaccination societies to resume their activities, but still forbids any public propaganda against vaccination as well as the exhibition of medical certificates allowing exemption from vaccination without medical examination.

SPECIALIZATION IN SPA TREATMENT

BALNEOLOGISTS IN CONFERENCE AT
HARROGATE

The value of spa waters in liver diseases and in skin affections, with special reference to the sulphur springs of Harrogate, was the subject of a medical conference arranged by the British Health Resorts Association at Harrogate on May 12th. The annual meeting of the Section of Physical Medicine of the Royal Society of Medicine was arranged to be held at Harrogate on the same date, with the result that a large number of balneologists and other members of the profession from London and elsewhere attended. The Yorkshire spa showed its usual hospitalities: a mayoral reception was held in the Winter Gardens, and the visitors were given the freedom of the Royal Baths, and inspected Harrogate's latest amenity, the sun promenade and pavilion in the Valley Gardens.

THE USE OF SPAS IN DISEASES OF THE LIVER

The first of the two discussions, on liver diseases (with Mr. D'OVLV GRANGE, president of the Harrogate Medical Society, in the chair), was opened by Professor W. LANGDON BROWN, who reviewed recent advances in the conception of hepatic metabolism. He said that the knowledge of the biochemistry of the subject had been extended and made more accurate by three discoveries during the last ten years: the discovery of insulin, which had made the whole story of carbohydrate much clearer; the discovery of the storage of certain haemopoietic factors in the liver, which had led to the practical rewriting of the pathology and treatment of the anaemias; and the quite recent discovery of the influence of choline on the fat metabolism of the liver. The liver helped to prepare all three food materials—proteins, fats, and carbohydrates—for utilization by the tissues. Its antitoxic functions included the process of rendering a poison harmless by conjugating it with a protective substance, also the formation of harmless glycuronates after administration of camphor, morphine, and the like. The liver was credited with playing an important part in anaphylaxis. Again, it was the principle stored in the liver which was essential to the formation of normoblasts from megaloblasts. He then went on to speak of the external secretory and the excretory functions of the liver, and of the recent work on the gall-bladder. One way in which hydrotherapy could definitely help followed from the idea now entertained that infection arrived at the gall-bladder by way of its surrounding lymphatics quite as much as by ascent of the common bile duct, and a gall-bladder filled with stagnant bile would easily fall a victim. Professor Langdon Brown concluded by saying that in a recent discussion on renal tests several surgeons expressed their willingness to abide by clinical signs alone. He himself was neither so bold nor so sceptical, but he urged that in Harrogate there were remarkable opportunities for scientific research into individual reactions to the therapeutic measures available at the spa.

Dr. J. W. McNEE said that simple cholecystitis was now stated to be the commonest intra-abdominal inflammation. In its treatment outside spas it was customary to give magnesium sulphate by the mouth in concentrated solutions. He thought that spa treatment should be able very effectively to deal with the more chronic stages, or even with the acute stages, of this condition. With regard to the true bacteriology and aetiology of cholecystitis, for some reason the practice of duodenal intubation had never gone to the length in this country to which it had gone in others, the main reason being that a wrong duodenal tube was used, one which did not pass easily through the pylorus. To be able to examine direct films of the centrifugized bile obtained by the duodenal tube afforded the greatest information as to the diagnosis and possible treatment of cholecystitis. Many chronic inflammations went smouldering on indefinitely. In what way could spa treatment come to the aid of the physician in these cases? Here he made a special reference to

dietetics. In hepatic and biliary diseases the question of the diet of the patient was of the greatest importance, particularly in chronic cases. When the patient was under one's care in his own home the dietetics could be to some extent controlled; in the spa this was less easy, and he pleaded for a much closer co-operation in British spas between the doctor, the patient, and the hotel manager as regards the diet of the patient undergoing the courses.

Dr. WILFRID EDGEcombe (Harrogate) outlined the clinical aspects of the treatment of disorders of the liver by the spa methods there available. The treatment was based on the use of the old sulphur water internally, the application of liver packs externally, and the use of baths—the strong sulphur bath or the massage douche. The strong sulphur baths were extensively used in the treatment of liver affections by the spa physicians of a generation ago, but were not so commonly prescribed now. The spa physicians to-day made more use of the massage douches than of the sulphur baths, in alternation with the liver pack. The Harrogate treatment of "congestion of the liver" was strikingly effective; the strong sulphur water had an almost specific action, the liver packs producing active counter-irritation and reducing visceral congestion, the sulphur baths inducing a determination of blood to the surface, and the massage douches accelerating interchange of tissue fluid.

Dr. C. W. CURTIS BAIN (Harrogate) described some interesting experiments with the sulphur water and its effect on liver disorders. He mentioned that in cases showing marked enlargement of the liver he had not been able to satisfy himself that alcohol was a factor more than in other groups, and he put forward the suggestion that alcohol had no effect upon the normal liver, but once there was a cholecystitis with a secondary hepatitis then alcohol became a poison to the liver. In a number of cases of varying degrees of disorder he endeavoured to assess the reasons for recovery. Three factors should be taken into consideration: the spa atmosphere, the liver pack, and the sulphur water. He had carried out experiments, mostly on himself, with the duodenal tube, and these had suggested that the cholagogue effect of the sulphur water (20 c.cm. of which was administered down the tube) was very similar to that of olive oil. Although his experiments were still incomplete, it could be said that sulphur water was a powerful cholagogue, perhaps the most potent in therapeutics; but it could not be said yet why it was potent. He went on to suggest that Harrogate waters might have specific properties for the treatment of liver disorders. Nobody had yet produced, he said, any satisfactory evidence to show that sulphur water, taken internally, had an influence upon the rheumatic group of diseases, but if the primary effect of sulphur water was shown to be on the liver the result might be some much desired specialization among spas, and it would be possible to give an answer to the cynic who asked how it was that the waters of Bath, Buxton, and Harrogate were all so successful in curing the same diseases when they differed from each other as much as chalk from cheese.

Professor D. P. D. WILKIE (Edinburgh) laid it down that in well-established cases of infection of the biliary passages with gall-stones surgery was the rational treatment and the only form of treatment wholly successful; but if surgery was to be undertaken the preliminary preparation of the patient was as necessary as the operation itself. For many patients the operation was as great an ordeal as the boat race for the undergraduate, and what would be said supposing a preliminary purge were the only preparation for the boat race? He referred to the diminishing mortality in cholecystectomy, due in part, no doubt, to increasing surgical experience, but in the main to increased attention to the pre-operative regime, in which diet and exercises played an important part. Professor Wilkie also mentioned that when cholaemia supervened benefit had been found by giving diathermy through the lower part of the chest; this was comparable to the liver pack given so effectively at Harrogate. He felt that in modern abdominal surgery, particularly of the biliary tract, it was needful to get away from a purely mechanical pathology and anatomical outlook and to remember that they were dealing not only

with obstruction from stone or irritation due to stone, but with a disordered physiology which affected the liver.

Dr. P. H. MANSON-BAHR spoke from the point of view of tropical medicine, and mentioned incidentally that tropical medicine had now come almost to the end of its war against parasites. It had an armamentarium against the diseases with which it had to deal the like of which was possessed by no other branch of medicine. Nothing like the same number of people were found returning from the Tropics with active parasites in their blood, and he humorously suggested that there was need for a new society for the preservation of diseases that were rapidly becoming extinct! "Tropical liver," however, was still a problem; as to whether there was such a thing he quoted Sir Patrick Manson, who said that he himself had suffered from it in early days in China. One would like to send many cases of tropical disorders to Harrogate, but he himself was not clear as to the advisability of sending people who had had properly diagnosed dysentery to Harrogate for after-treatment. It was one thing to eradicate the parasite and another thing to irritate the intestinal tract. If the case was one of amoebic dysentery, and a cure could be promised, he did not think that after-treatment should consist in douching out the bowel with large quantities of irritating waters.

Professor LANGDON BROWN, in summing up the discussion, endorsed Dr. McNee's plea for more definite control over the dietetic treatment of patients while at spas. It was a common experience that patients who went to Continental spas were more prepared to "toe the line" in this respect than those who went to British spas, the reason being the lack at the latter of definite and authoritative regime.

THE SPA TREATMENT OF SKIN DISEASES

The second discussion, over which Dr. M. B. RAY, president of the Physical Medicine Section of the Royal Society of Medicine, presided, was opened by Dr. S. ERNEST DORE, who remarked that, with some notable exceptions, it seemed to him that the present trend of opinion favoured the theory of exogenous causation of the eczematous group of skin diseases. He doubted whether Harrogate practitioners would altogether subscribe to the view that eczema had its origin from external causes. Simple protection of the skin of patients so affected from all possible forms of external irritation was not enough to secure removal of the disease, and in the more chronic cases some form of stimulating treatment by means of various local medicaments—including sulphur baths in suitable cases—combined, if thought necessary, with sulphur internally, colonic irrigation, or other measures, might be required. The question of the relative importance of the external and internal treatment of skin diseases was one which he would like to hear discussed by Harrogate practitioners with their unrivalled opportunities of comparing the two. Dr. Dore went on to indicate on broad lines certain groups of skin diseases which were suitable for spa treatment. He uttered a word of warning against the indiscriminate and excessive use of sulphur in any cutaneous affection. He so often saw severe dermatitis and pruritus caused by its ill-judged or protracted application that he felt such a caution to be very necessary. Sulphur was a two-edged weapon, and Spartan methods of employing it were apt to react upon the practitioner as well as on the patient and the spa at which he was being treated.

Dr. H. HALDIN-DAVIS referred to the advantage of spa treatment in those skin diseases which were particularly associated with conditions of anxiety and neurasthenia, of which lichen planus was the most typical. This condition was one which, above all, did well when treated away from home, and preferably at a spa. He expressed himself in favour of the internal rather than the external use of the water. The eliminatory properties that Harrogate water enjoyed had a beneficial effect on many types of dermatoses which he thought far more important than the external employment of the various springs. Dr. F. A. BEARN spoke of skin diseases which he had seen

and treated during twelve years' practice at Strathpeffer. Only two types stood out as giving really satisfactory results—namely, the so-called gouty eczema, and psoriasis arthropathica—and one was struck at once with the fact that these were not cases of skin diseases at all but skin manifestations of metabolic disorder. Dr. W. BERTRAM WATSON (Harrogate) summarized the results of a long and varied clinical experience of the spa treatment of skin diseases, fully agreeing with Dr. Dore that the trend of present opinion favoured the theory of exogenous causation of the eczematous group. Cases of psoriasis which did best were those in which the eruption was widespread and neither progressive nor hyperaemic—psoriasis inveterata. It appeared that the proportion of cases of cutaneous disorders dealt with at Harrogate was declining over recent years. From the records of the Royal Bath Hospital five times as many skin patients were treated there in the first ten years of this century as in the last ten years. There were, however, fashions in medicine as in everything else, and he believed that the pendulum would swing back.

Dr. J. C. BUCKLEY took up a remark of one speaker that in acute or subacute eczema water ought not to be applied; yet he was under the impression that in these conditions they were told that sedative lotions were the proper treatment, and, after all, what was the basis of a sedative lotion but water with some slight mineral or organic mixture; and what was spa water but water of that character? Dr. EDGECOMBE said that in treating these conditions a great deal depended on the soil as well as the seed, and this applied not only to cases of so-called constitutional dermatitis, but also to the whole group of the allergic type—the chronic urticarias. Patients in this group could be rendered less susceptible to the irritating agent by a course of internal treatment in addition to the external.

Dr. ALFRED COX, secretary of the British Health Resorts Association, before the discussion concluded, made a few remarks on the management of spas, and expressed the view that what the average member of the public wanted when he went to a spa for treatment was to be taken, figuratively, by the scruff of the neck and told exactly what to do. British spas had doctors of great skill and experience, they had waters of proved value, but there was still something lacking in the organization and authority which they needed to cultivate.

In the evening the Harrogate Medical Society were the hosts at a dinner at the Hotel Majestic. In reply to the toast of the health of the British Health Resorts Association, Lord MESTON, the President, gave a brief outline of its achievements and intentions, and said that there was no desire on the part of anybody concerned to decry or depreciate the great thermal institutions of the Continent. There was much in Continental spas which was worthy of imitation, and a good deal to incite envy, especially the way in which they were subsidized and patronized by the State; but it was felt that British resorts represented a great national asset of which full use had by no means been made. The MAYOR OF HARROGATE (Councillor Newsome) mentioned that although the waters had been known for three centuries Harrogate as a town was comparatively modern, celebrating this year, indeed, the jubilee of its incorporation. The recent provision of the new sun walk and pavilion was only part of an extensive scheme, which was to include a new pump room.

The Royal Waterloo Hospital is accessible for people living in some of the poorest parts of London and southern England, and the calls on its out-patient department have recently become embarrassing in their number. During the past ten years the number has increased from 50,973 to 83,680 per annum. Such an increase has made extension an urgent necessity, and the 118th annual report refers to proposals for building on the further side of Waterloo Road, though no definite action can be taken till the scheme has been approved by King Edward's Fund.

England and Wales

The Liverpool Medical School

In connexion with last week's celebration of the centenary of the Liverpool Medical School (see p. 905) a brief record of its history has been prepared by Dr. A. A. Gemmell and published as a pamphlet.¹ The Liverpool Royal Institution School of Medicine and Surgery was founded in 1834, but ceased to exist ten years later, its work being continued by the Royal Infirmary School of Medicine. The origin of medical teaching in that town is actually traceable to 1789, when the requirements of the slave trade necessitated the testing of ship surgeon candidates by the medical board of the Liverpool Infirmary. There are definite records of lectures as far back as 1811, and before 1826 the staff of the Infirmary, especially the surgeons, had private pupils who worked in the wards. Private teachers flourished in Liverpool in the early part of the nineteenth century. In those days students worked for about four years in the wards, and then went to London for a year of lectures and "walking the hospitals" before they could sit for their professional examination. Although teaching was carried on in buildings on the Infirmary grounds, the cost of furnishing had to be met by the lecturers, who each contributed £5 for the purpose. The lecturer in chemistry refused to subscribe, since he had already been obliged to rent the laboratory at the Royal Institution in order to start his classes. In 1846 the trustees of the Infirmary assumed certain liabilities in respect of the outside repairs to the buildings and the supply of gas, coal, and water, but the remainder had still to be financed by the lecturers. A rota of the honorary staff for giving clinical lectures is first noted in 1849, and a year later prizes were established in clinical medicine and surgery. In 1852 the lecturers offered a gold medal to the best student of the year, and the committee of the Royal Infirmary agreed to grant to the successful candidate a free residence in the house, with a free clerkship and dressership for six months. The Northern Hospital had been opened in 1833, and some little time before 1852 pupils were admitted to it. In 1857 the Southern Hospital, with one hundred beds, became recognized as a teaching hospital by the Royal College of Surgeons, but the Royal College of Physicians did not grant recognition until 1870. The Royal Infirmary School of Medicine steadily developed, and in 1881 a charter of incorporation of University College was obtained, work commencing the next year on buildings erected on a site previously belonging to the Royal Infirmary. In 1884 the College became a part of Victoria University with the Colleges of Manchester and Leeds. The closing years of the nineteenth century saw great advances in all directions with the growth of modern medical science, and eventually the charter of the University of Liverpool was granted in 1903, establishing simultaneously a guild of undergraduates. Since then progress has been rapid, recent outstanding achievements being the reconstruction of the department of biochemistry in 1932, and of the departments of physiology and pathology last year.

Village Hygiene

A Chadwick Public Lecture, entitled "Village Hygiene: Water supply; Disposal of Refuse," was given by Dr. Jane Walker, C.H., on May 8th, at the Royal Society of Tropical Medicine and Hygiene. She began by stating how much more attention had been paid to sanitation in towns than in villages, and how little material there was for such a lecture. Indeed, Dr. Vivian Poore's *Rural Hygiene* was still the only standard work on the subject.

¹ *The Liverpool Medical School, 1834-1934. A Brief Record.* By Arthur A. Gemmell. Liverpool: University Press; London: Hodder and Stoughton, Ltd. (1s)

and that was published in 1894. Dr. Vivian Poore was a great friend of the lecturer, and helped her in arranging the sanitation for her sanatorium in Suffolk for the open-air treatment of tuberculosis. The methods of refuse disposal, established in 1901, were then detailed and the contemplated change to water carriage discussed. Reasons were also given which made such a change imperative, deplorable as they were. The value of the dry system of sewage disposal, from a manurial point of view, was stressed, and the difficulties of dealing with large quantities of refuse water were pointed out, also the fact that sewage must be diluted enough not to kill, but really to nourish plant life. The value of rain water and the importance of conserving it was dwelt on, and a method of rendering it pleasantly drinkable was described. The duties of rural district councils in providing pure and sufficient water for everyone, and the various Acts and by-laws with this requirement were touched upon. The lecturer mentioned the Homecroft Association, founded in 1926, which is interested in promoting rural dwellings on the margins of towns for industrial workers and giving them land enough to produce food for their own tables in their spare time, thus enabling them to live a healthy life. Dr. Walker finally pointed out how a cottage could be kept clean and wholesome, and drew attention to the Leeds plan of providing new furniture and bedding for their new housing scheme, thus preventing the charge being made against slum dwellers that they became such wherever they were. The four "acid tests" for hygienic arrangements in the country were: (1) Are they efficient? (2) Are they easy to use? (3) Are they inexpensive in installation? (4) Are they sightly?

Central Midwives Board

At its May meeting the Central Midwives Board for England and Wales agreed to reply to a letter from the Ministry of Health that the Board did not consider that the new rules in Section E could be circulated in sufficient time to enable local supervising authorities, midwives, and any other bodies and persons concerned, to become conversant with them by July 1st next, and that therefore it would be glad if the Minister could see his way to approve the existing rules until October 1st next, on which date the Board considered that these rules should become operative. It was reported that the following resolution had been received from the Queen's Institute of District Nursing:

"That the Central Midwives Board be asked to call the attention of its members representing the Society of Medical Officers of Health, the County Councils Association, and the Association of Municipal Corporations, to the number of necessitous cases which are referred by doctors to midwives with a request that they should be summoned by a medical aid form, though the patients have been under medical care and suffer from complications due to general illness which renders them unsuitable to be midwives' cases."

It was agreed to inform the London County Council, in reply to a letter received from it:

Rule 10.—(a) That a midwife must not, except under a grave emergency, undertake operative procedure or any treatment which is outside her province. *Note.*—The question whether in any particular case such procedure or treatment was justified, will be judged on the facts and circumstances of the case.

(b) A midwife must not, on her own responsibility, use any drug unless in the course of her obstetric training, whether before or after enrolment, she has been thoroughly instructed in its use and is familiar with its dosage and methods of administration or application. *Note.*—The Board, for example, would regard the giving of pituitary extract before the birth of the placenta, except under a grave emergency, as treatment outside a midwife's province.

A study of these rules will show that in grave emergency it will be permissible for a midwife to adopt the procedure in question, and the Board will be glad to know, in due course,

the results of the Council's experience of the working of this treatment.

Approval as lecturer was granted to Dr. Gertrude Elizabeth Cuttle, Dr. J. G. H. Ince, Dr. P. G. S. Kennedy, and Dr. J. V. O'Sullivan.

Guy's Hospital Radiographic Departments

Sir Albert Levy, who is a governor of Guy's Hospital, visited the hospital's radiographic departments on May 9th to see the working of the new equipment which has recently been provided by a gift of £6,000 from the Albert Levy Benevolent Fund. Creating the fund in 1929 for the purpose of assisting hospitals and other charitable objects, and alleviating distress and poverty, Sir Albert Levy transferred to the trustees of the fund securities to the total value of £250,000, the deed of settlement providing that, in addition to the annual distribution of the income received, the trustees should distribute the whole of the capital in twenty-five yearly instalments. The cash to be received and distributed by the trustees during the operation of the fund, therefore, will amount to upwards of £400,000. During the five years of its existence the fund has benefited a large number of important charities of all kinds, and grants have also been made to individuals in relief of poverty. Upwards of sixty hospitals have received grants, in particular the Royal Free Hospital, where a wing, opened by Queen Mary in 1932, bears Sir Albert Levy's name, and Guy's Hospital, where the radiographic departments have been entirely re-equipped at a cost of £6,000. At Guy's 14,608 patients were x-rayed in 1933 (23,377 photographic films and 5,361 screen examinations).

Scotland.

Annual Meeting of the British Association

The annual meeting of the British Association for the Advancement of Science will be held in Aberdeen from September 5th to 12th inclusive, under the presidency of Sir James Jeans. Previous meetings took place in that city in 1859, when the Prince Consort delivered the presidential address, and in 1885. On the present occasion Sir James Jeans will address the inaugural meeting on September 5th at 8.30 p.m., his subject being "The New World-picture of Modern Physics." There will be two evening discourses. The first, on September 5th, will take the form of a memorial lecture for the late president, Sir William Hardy, and will deal with the preservation of meat, fish, and fruit. The second will be delivered by Professor W. L. Bragg on September 10th on the exploration of the mineral world by x rays. It is also hoped to arrange an evening symposium on September 11th on the general relation between science and the community. The Sections this year will be: mathematical and physical sciences, chemistry, geology, zoology, geography, economic science and statistics, engineering, anthropology, physiology, psychology, botany, educational science, and agriculture. The presidential address in the Section of Physiology will be delivered by Professor H. E. Roaf on normal and abnormal colour vision, and there will be papers and discussions on nutrition in relation to disease; food preservation; and recent contributions to the physiology and pathology of the blood. Dr. Shepherd Dawson's presidential address in the Section of Psychology will deal with psychology and social problems. In this Section there will be a joint discussion with the Section of Zoology on the interpretation of animal behaviour, and another joint one with the Section of Educational Science on some aspects of child guidance. Other papers and discussions will relate to perseveration and its testing,

and the measurement of fatigue. In connexion with the annual meeting whole-day excursions will be made on Saturday, September 8th, to Inverness, Morayshire, Deeside, the Grampians, the Trossachs, and other centres of interest. The programme and daily time-table of the meeting will be forwarded in August to those who have intimated their desire to attend; and with it will be issued copies of *The Scientific Survey of Aberdeen and District*. Inquiries about membership should be addressed to the secretary, British Association, Burlington House, London, W.1. It is announced that future annual meetings will be held at Norwich in 1935, at Blackpool in 1936, and at Nottingham in 1937.

Victoria Hospital Tuberculosis Trust

At the annual meeting of the Royal Victoria Hospital Tuberculosis Trust, held in Edinburgh, Sir Ralph Anstruther, referring to the decline in the tuberculosis mortality rate, said that this was due in part to the work of the Trust for many years past. He believed that at the present time insufficient attention was being paid to the incidence of tuberculosis among children. Dr. A. H. H. Sinclair, President of the Royal College of Surgeons, stated that Southfield Sanatorium, managed by this Trust, was largely intended for the treatment of tuberculosis in its earliest manifestations, and one-quarter of the patients there were children. He had been an assistant in the Victoria Dispensary in 1896, and the feature which distinguished the work to-day from that of forty years ago was the attention now given to research. Professor Sir Robert Philip, vice-president of the Trust, said that a curious idea was abroad that when the Government of a country took an interest in a movement, voluntary effort might sink into the background. This was a great error. The Government had provided, as no other Government in the world had done, a tuberculosis scheme working efficiently throughout the country on a uniform pattern. Beyond this, however, there was much work which could only fall to be done by such agencies as the Trust in virtue of the fact that the Trust was a free agent. Among other things, the Trust was concerned with educating public opinion and also doctors, and mitigating, as far as possible, the difficulties which overtook households when tuberculosis entered the doors. A large measure of success in any campaign depended upon the intelligence department, and the Trust claimed through its research work to form a part of that department in the campaign against tuberculosis. Much success had already attended its efforts: during the past twenty-five years the tuberculosis mortality rate had fallen by 50 per cent. Dr. William Robertson, formerly medical officer of health for Edinburgh, said that the Trust had taught local authorities all over the country how their work should be organized. The report of the Trust for the past year points out that forty-six years ago practically nothing was done towards the control of tuberculosis. Since then, however, mortality had fallen steadily. The Trust, while watching every part of the field, had decided to focus its energies especially upon questions attaching to the tuberculous child. The modern view was that infection occurred in various ways during childhood, and this influenced the whole life of the individual. The child should be protected, therefore, first from the infection, and secondly from its more serious consequences, which might disturb health or cause death at any subsequent date. Research work at Southfield Sanatorium continued to be directed to the avenues of infection and the channels of spread, and it was becoming more and more clear that tuberculosis in the adult was simply a late consequence or end-product of the infection. With regard to diet, the committee, through long experience, had become convinced of the great value of fresh fruit and vegetables,

eggs, raw meat, fresh milk, and butter, with a limitation of certain carbohydrates. Each case, however, should be considered on its merits—for example, in intestinal tuberculosis the value of fresh tomato juice had been confirmed. The strict limitation of salt in many forms of tuberculosis had also been found beneficial. Investigations had been renewed to determine the place of sheep's brains in the dietary. Observations on patients who were making slow progress on ordinary diet showed that coincidentally with the addition of brains noteworthy improvement occurred in respect of checking systemic and circulatory disturbance. The report appeals for help for research work, and states that the trustees of the late Mr. W. L. Stewart have allocated £750 to provide the salary of a research scholar for three or four years, but that much more is required for prolonged investigation, a sum of £5,000 being desirable. Appended to the report is considerable information concerning the handling of cases of tuberculosis, and the rules for the maintenance of health by tuberculous patients.

Glasgow Post-Graduate Courses

A summer session for post-graduate teaching has again been arranged under the auspices of the Glasgow Post-Graduate Medical Association. The facilities will fall chiefly into two divisions: (a) general medical and surgical course, and (b) clinical assistantships. During the last two weeks of August and the first two of September a whole-time course, for which an inclusive fee is charged, will be conducted in some of the general and special hospitals. The course will include most of the subjects of interest to the general practitioner—the mornings being occupied with general medicine and surgical diagnosis, and minor surgery in the Royal Infirmary and the Victoria Infirmary, and the afternoons with special subjects in the special hospitals or departments of the general hospitals, two subjects being dealt with each afternoon. Clinical assistantships, which are limited in number, are available in the summer months as well as at other times. Full particulars may be had from the secretary, Post-Graduate Medical Association, The University, Glasgow.

Central Midwives Board

The results of the recent examinations of the Central Midwives Board for Scotland, held simultaneously in Edinburgh, Glasgow, Dundee, and Aberdeen, were as follows. Out of 165 candidates who appeared for the examination, 147 passed: of the successful candidates twenty-five were trained at the Royal Maternity Hospital and twenty-one at the Elsie Inglis Memorial Hospital, Edinburgh; fifty-six at the Royal Maternity Hospital, Glasgow; five at Stobhill General Hospital; two at the Eastern District Hospital; one at the Western District Hospital; six at Govan Maternity Hospital; eight at Bellshill Maternity Hospital; one at Barshaw Hospital, Paisley; three at the Maternity Hospital, Aberdeen; fourteen at the Royal Infirmary, Dundee; and one at the Royal Infirmary, Stirling.

Presentation to Larbert Doctor

At a public meeting in Larbert on May 10th a presentation was made to Dr. John Gilfillan Ronald, who for forty-three years has been a medical practitioner in the district. The chair was occupied by Sir Ian Bolton, and a number of Dr. Ronald's former assistants, now practising elsewhere, were present. The occasion was the centenary of the commencement in practice of Dr. Ronald's father: the latter retired and was succeeded by his son in 1891. The presentation was made on behalf of the community of Larbert by the Rev. D. S. McEwen, and took the form of a silver loving-cup suitably inscribed and a cheque for £268.

Reports of Societies

SELF-ADMINISTERED ANALGESIA FOR THE MIDWIFERY OF GENERAL PRACTICE

At the meeting of the Section of Anaesthetics of the Royal Society of Medicine on May 4th, with Dr. H. P. FAIRLIE in the chair, a paper was read by Dr. R. J. MINNITT (Liverpool) on "Self-administered Analgesia for the Midwifery of General Practice." The paper was accompanied by a film.

Dr. Minnitt began by a reminder of the great mental and physical suffering of women in labour. In the relief of labour pains three principles were taken: (1) the procedure must be simple and inexpensive; (2) there must be no danger to either mother or child; (3) labour must not be prolonged by the means adopted. He was satisfied that his gas-air analgesia technique satisfied these requirements. He used the term "analgesia" as indicating insensibility to pain without loss of consciousness. The gas-air analgesia apparatus which he demonstrated weighed, including face-mask, seven and a half pounds. The average consumption of gas was thirty-five gallons per hour, and analysis of the mixture inhaled showed approximately 35 per cent. nitrous oxide in air. The whole action was controlled by inspiration. The apparatus was never intended for inducing anaesthesia, hence it was not applicable for such procedures as version, the application of forceps, or any extensive repair of a torn perineum. The only important instruction was that whoever applied it must see that it fitted the face in an airtight manner. Scientific work showed that there was no danger to mother or child in its use, and electrocardiograms taken before and during application bore out this fact. The report of the medical officer in charge of the electrocardiograph department of the David Lewis Northern Hospital on six patients was that the electrocardiograms did not appear to have been influenced to any significant extent as the result of the patient's experience. The alterations in the mother's pulse and the foetal heart rates estimated at approximately equal intervals during analgesia were within normal limits. He was unable to submit scientific evidence that labour was not prolonged, but the average length of the second stage in normal deliveries with gas-air analgesia for eighty-one primigravidae, making use of the analgesia for varying times from fifteen minutes to nine hours, including delivery, was one hour and eighteen minutes, and in a total number of forty-seven multigravidae, making use of analgesia for varying times from fifteen minutes to four and a half hours, including delivery, the average length of the second stage was thirty-five minutes. The inference was that the length of the second stage of labour was within normal limits. Finally, there could be no question about the relief from pain and distress due to the use of the apparatus: the cinematograph film demonstrated it. In his wards there was comparative quietude; patients were less tired than formerly from their efforts at expulsion; and amnesia was produced, sometimes until the next day, patients avowing that they did not remember anything about delivery. The report on the method given by the medical board of the Liverpool Maternity Hospital stated:

"From their own observations the members of the board are satisfied that the method does relieve pain without interfering with the progress of labour, and without ill effect on the mother or child. The recent observations on the electrocardiographic readings and the blood gases support the clinical findings from the experimental point of view, and it is hoped that further work of this nature will be undertaken.

"The method is simple and safe: the apparatus is portable and admirably adapted for use in domiciliary work in the hands of any well-trained midwife. Arrangements have already been made for the instruction of nurses in the administration of this form of analgesia, and it is hoped that the method will be introduced into district work in the near future."

Dr. JOHN ELAY spoke of having used the method for 141 cases at Wellhouse Hospital, Barnet. There were five failures. He made a practice of getting the apparatus

going and assuring himself that the patient was all right, after which she was able to carry on. No premedication was used, though one or two of the patients had had a little morphine earlier in the labour. In his opinion the method was the greatest advance that had been made in order to bring the advantages of anaesthesia in labour to those women who were attended only by midwives or nurses, or even busy general practitioners.

Miss LLOYD WILLIAMS (Royal Free Hospital) said that the apparatus had been in use at her hospital for three weeks, and during that time it had been used on twenty-nine cases, all but one of which were primiparae. All except one received some form of sedative treatment beforehand. In twenty-seven of the cases the gas-and-air was given only for the second stage; in the other two it was given also at the end of the first stage. In the twenty normal cases there was good analgesia in nine, fair in six, and poor in five. Though gas-and-air was a good analgesic, she and her colleagues did not feel that it was adequate to tide the woman over the actual birth of the child, therefore in most of their cases some anaesthesia was used—in most, chloroform.

Dr. GEMMELL (Liverpool Maternity Hospital) said that it should be emphasized that the method of self-administration left the doctor's hands free; the instruction to the patient as to its use could be carried out while the doctor was preparing his hands. The use of the apparatus certainly lessened the voluntary resistance of the patient, and so tended to shorten the second stage. He had specially noted the restfulness of the mother between the pains, and that at the end of labour she was much less tired than had previously been the case. He did not foresee any emergencies, except total failure of the apparatus; the larger problem would be as to how midwives could obtain the use of the apparatus, the cost being beyond their private means.

Dr. HILDA GARRY (Liverpool Maternity Hospital) said that the use of the apparatus by hysterical patients was sometimes difficult, but in the great majority of cases the analgesia was administered entirely by the patient herself during delivery. In many there was complete amnesia, and the woman would say she had no pain. She did not think that perineal tears were more frequent or serious with the apparatus than without it. She had conducted 121 cases at the Liverpool Maternity Hospital, and in 103 there was good relief from pain. These included three forceps deliveries, all after prolonged second stage, the patients receiving analgesia up to the time of the general anaesthetic. The eighteen poor results were classified under tardy administration, dislike of gas, non-cooperation, hysteria, and other causes.

Dame LOUISE McILROY said that her view was that the period of most acute pain was at the end of the first stage; even the passage of the head did not cause quite so much pain as that. The majority of the cases at her hospital had light chloroform, or ether, or gas-and-oxygen when the head was passing over the perineum. The great point in this apparatus was the self-administering factor, though it should not be used, she thought, without supervision, either by doctor or nurse, as she would hesitate to regard it as completely foolproof. She hoped the apparatus would be produced cheaply; it would be interesting to know that various hospitals were trying it. It seemed likely to solve the problem for the midwives of the future.

Dr. L. C. RIVETT reminded the meeting that more than half the confinements in the country were conducted by midwives without a doctor, and this would be a boon to them. The machine described had been used at Queen Charlotte's Hospital for three weeks, on twenty-five cases. About half the patients said that they had no recollection of the birth of the child, and nearly half said the pains were very much relieved, though they did remember the birth. There had been no delay in the second stage of labour; if anything, the apparatus shortened the second stage, at the same time reducing the patient's voluntary response to the progress of the child's head. From what he had seen of the apparatus he had nothing but praise for it. Miss KELLY spoke of her experience of the apparatus in eighteen cases, in only three of which was it unsuccessful. Two of the three were very hysterical

women who could not be persuaded to help in any way. Dr. WADDY said he had seldom found the ordinary analgesia sufficient for the delivery of the child's head. He also expressed some anxiety about cases when the heart was not very strong, as the midwife was not likely to be able to deal with the emergency which might happen at the height of the pains. Dr. WRIGLEY believed that the widespread use of such an apparatus would ensure a much greater number of normal deliveries.

Dr. MINNITT, in reply, said that he had tried a number of patients with a small dose of scopolamine, but it seemed to make them too drowsy, and that might delay the pains. There were two conditions in pregnant women which, with gas, produced cyanosis—namely, serious heart disease and lung disease—and a midwife should not allow cyanosis when using this apparatus without calling in a doctor.

THE GALL-BLADDER IN VARIOUS ASPECTS

A meeting of the Clinical Section of the Royal Society of Medicine on May 11th, under the chairmanship of Dr. BERNARD MYERS, was devoted to the consideration of the gall-bladder from various aspects.

ANATOMY AND CONGENITAL ABNORMALITIES

Professor H. H. WOOLLARD, in discussing the anatomy of the gall-bladder, said that in some mammals the gall-bladder was absent. It might be absent or present in closely related members of the same genus. These variations were somewhat obscure. It had been stated that if was the intermittent feeders who possessed a gall-bladder, but not much value need be attached to that distinction. In those animals which had not a gall-bladder, such as the rat, the bile from the liver was a much more concentrated liquid than that which occurred in animals with a gall-bladder; therefore there seemed to be an intrahepatic concentration of the bile. He reminded the meeting of the general position and anatomical relationships of the gall-bladder. It had been suggested that the adjacent relationships, such as the pressure of the abdominal wall or the respiratory excursions of the liver, might have something to do with the emptying and filling of the gall-bladder, but the speaker considered it improbable that any of these structures were concerned. Very great variations were possible in the normal anatomy. The gall-bladder might be buried within the liver. In one in 3,000 it showed a tendency to be double. A host of anatomical variations were present with such frequency that one could not well talk about a normal structure, and it seemed clear from radiological studies that none of these anatomical variations was of any importance; it was always possible, whatever the variation, for the gall-bladder to empty itself sufficiently. The musculature of the gall-bladder was poor, not arranged in any regular strata; outside the muscle wall there was a perimuscular layer in which blood vessels and lymphatics were abundant. The movements of the gall-bladder had been intensively studied. It had been said that nobody had ever seen it contract or had observed peristalsis within it, but, despite this, there could be no doubt that the gall-bladder did contract and that the contraction was associated with a relaxation of the sphincter of Oddi. Various drugs, such as pituitrin and pilocarpine, would stimulate the gall-bladder, as would ingestion of foodstuffs, or even the anticipation of food, such as cream and yolk of egg, also the circulation of chemical substances. It appeared that the movements were initiated in the first instance by nervous reflex, and subsequently maintained by chemical activity. The speaker showed examples of the anomalies in the hepatic duct system; some 320 variations had been described, and it was impossible to reduce them into a classification. One had simply to be prepared for almost anything.

PHYSIOLOGY, PATHOLOGY, AND CLINICAL ASPECTS

Dr. CHARLES NEWMAN said that the function of the gall-bladder was twofold: concentration, and emptying and filling activity. The important question was what was added to the bile and taken from it during its stay

in the gall-bladder. The fact that the gall-bladder did empty was accepted by everybody. The nervous mechanism was of some importance, the vagus being the stimulating nerve to the muscular apparatus. Strong stimulation of the vagus caused spasm in the muscle. The strongest muscle in the biliary system was the ampulla, but mucous secretion from the walls of the bile ducts would produce a very high pressure in the system—much larger than the gall-bladder could produce or the ampulla could withstand, even when in a state of spasm. The abnormal physiology of the gall-bladder was very much the same whatever the disease of the biliary tract—that is to say, the effect of spasm of the ampulla or stasis of the biliary system was very much the same whatever the cause producing it—hence the extraordinary similarity of the symptomatology in gall-bladder disease. He believed that cholecystitis, if sufficiently definite to be diagnosed, should be treated by operative procedure, and not by medicine. The only difficulty was to be certain of the diagnosis of cholecystitis, which might be classified into three groups—namely, acute, chronic with gall-stones, and chronic without gall-stones. The patient with genuine chronic cholecystitis usually suffered from flatulent dyspepsia. The bile recovered with the duodenal tube, apart entirely from the information obtained as to the way in which it was expelled, was of some value in showing whether the gall-bladder was inflamed or not. Cholecystitis was a subserous inflammation, and not a submucous one. The theory of gall-bladder infection had passed through certain phases. The original suggestion was infection with *B. coli* which had got into the gall-bladder; then it was thought to be staphylococci, and again streptococci; and now there was a very strong return to the original doctrine that the agent was usually *B. coli*. The way in which the organism got there presented an equally difficult problem; so little was known concerning it that it was not worth quarrelling over the subject. Dr. Newman went on to discuss the nature of the gall-stones, and the arguments that the pure cholesterol stone might be due to metabolic changes. He felt himself that it was probably produced by very mild infections of the gall-bladder. Cystic duct obstruction was the conditioning factor for the production of excessive calcium in the gall-bladder. Carcinoma of the gall-bladder was commonly supposed to be due to gall-stones, but one-third of the cases of carcinoma were found in stone-free gall-bladders, and it was much more likely on statistical grounds that both gall-stones and carcinoma of the gall-bladder were due to cholecystitis, and not the carcinoma of the gall-bladder to the gall-stones. It was said by many people that the gall-bladder was never palpable, and while Dr. Newman did not wholly agree with this he thought that sometimes the clinician felt a single segment of the rectus and thought it was the gall-bladder, largely because his clinical sense suggested that the patient was likely to have a distended gall-bladder.

RADIOLOGY

Dr. H. K. GRAHAM HODGSON discussed the radiological appearances. Radiology never would take the place of routine clinical methods; its real purpose was ancillary, and it was not the spearhead of the diagnostic attack. He demonstrated how far it was possible for the radiologist to assist in the diagnosis of pathological conditions in the gall-bladder. He divided the history of the subject into two distinct eras. The first was from 1899 to 1924, when the increasing refinements of x-ray technique helped in the ascertainment, the limiting factor being the calcium content of the stones, for unless this calcium content was sufficiently large, gall-stones were not opaque to x rays. In considering opacity it must be remembered that radiography was based on relative and not absolute opacities, and a stone removed from the gall-bladder might cause a ray shadow, whereas in the body it could not be differentiated from the shadows of the surrounding tissues. The second period, from 1924 onwards, had been one of marked advance in cholecystography through the use of a particular dye to bring about a difference in density. That

was largely a test of physiological capacity, in contrast to the almost wholly mechanistic nature of the opaque meal examination. In cholecystography a very careful technique was essential, the word "technique" including the previous preparation of the patient. The main physiological factors governing examination must be strictly observed. Forty-eight hours previous to the examination the patient should take a purgative. On the following day a control radiograph should be taken on a large film, to include the area of the lumbar and the lower dorsal spine. The patient should be carefully instructed to hold his breath, as the slightest movement made the faint shadow of a gall-stone invisible. The radiogram so taken should be carefully examined for renal calculi or any condition of the lower dorsal spine which might lead to error. The patient should take a prescribed meal in the evening, and half an hour after the meal the dye should be given. The patient should then be required not to eat or drink anything until the radiogram was taken fourteen hours after the ingestion of the dye. A further radiogram was usually taken at sixteen, or eighteen, and sometimes at twenty hours. It was in eighteen to twenty hours that the maximum degree of concentration was reached. With the aid of a number of radiograms Dr. Hodgson discussed the x-ray findings, and closed by remarking that cholecystography was still a young subject, and much had to be learned.

SURGICAL ASPECTS

Mr. A. J. WALTON said that, although cholecystitis was a common cause of formation of stones, cases of acute cholecystitis were rarely seen to-day without stones. He thought that one ought to be very chary of diagnosing cholecystitis without stones unless it had a very short history and had arisen more or less in the course of some acute infection elsewhere. If the condition appeared to be quietening down in a few days one was justified in watching it and seeing how it progressed, but if it became worse, then operation was necessary. The operation of preference was cholecystectomy, but if the patient was gravely ill cholecystostomy as a palliative might have to be undertaken. Chronic cholecystitis was a condition much too frequently diagnosed, and much too frequently operated on. If the patient had chronic cholecystitis he would ultimately develop gall-stones, and until the stones did develop, as a general rule, one would lose nothing by treating the patient medically, and the patient was in no grave danger. The danger to-day was in having cholecystitis too easily diagnosed and too easily operated on. If the medical treatment failed to give benefit the patient would probably develop gall-stones, which would make the diagnosis more assured. Many of the cases wrongly diagnosed as chronic cholecystitis were in fact due to altered function of the gall-bladder. He discussed the formation of the stones, mentioning that he had long maintained, on clinical grounds, that the pure cholesterol stone was not metabolic. This was indicated by the fact that it was always in its outer layers amorphous, that it was never in any circumstances found in the ducts, and that every such stone which he had seen had been associated with pathological evidence of chronic cholecystitis. He believed that all gall-stones, other than purely pigment stones, were secondary to chronic cholecystitis, and therefore should theoretically be operated on, though there were certain types of patients—especially those who were able to adapt themselves to the conditions of their disease—to whom it might be preferable to give medical treatment, and by a well-regulated course of medical treatment the patient might at any rate be put in a much better condition for operation ultimately. But operation must not be delayed too long. Mr. Walton gave some statistics of cases which had been under his care. Of his total number of gall-stone cases—namely, 862—the number in males was 149 and in females 513. There were 133 cases of stone in the common ducts—twenty-seven male and 106 female. Recurrent stone in the gall-bladder occurred in seventeen cases, in the common ducts in eleven, and in both in sixteen. His list included eighteen cases of carcinoma of the gall-bladder (four male and fourteen female), and twenty-eight of obstruction due to

carcinoma of the common ducts (eight male and twenty female). Of the eighteen cases of carcinoma of the gall-bladder twelve were without stones, and in the twenty-eight cases of carcinoma of the ducts twenty-one were without stones. These twenty-eight cases were referred as follows: ampulla, nine; common duct, six; junction, ten; hepatic duct, three. He would not agree with Dr. Newman that one could not feel the gall-bladder; he had felt it in dozens of cases. It was very interesting to watch a patient admitted to hospital with acute cholecystitis. During the first day there was pyrexia, but after a day or two the temperature fell and the condition improved, and then the gall-bladder could be felt. The symptom which was perhaps most helpful in diagnosis was the character of the jaundice. Intermittent jaundice in the case of a patient who had jaundice in the presence of gall-stones led to a combination of orange and red colours in the skin, which was unmistakable.

MEDICAL TREATMENT OF CHOLECYSTITIS

Dr. A. F. HURST said that he believed chronic cholecystitis to be the most common organic cause of indigestion. He stressed the enormous value of cholecystography if combined with palpation. One of the most important signs of gall-bladder disease was to find the point of tenderness at what one took to be the gall-bladder, and it was useful to have one's opinion of the location verified or otherwise by the x-ray picture. He made a plea for the greater use of the duodenal tube, which revealed many cases of what he would call medical cholecystitis in which the cholecystograph was perfectly normal. He did not quite agree with the way in which Dr. Newman had dismissed the question of infection, and he believed that the finding of *B. coli* in the bile was of the greatest importance, particularly if, by careful examination of the duodenum before the magnesium sulphate was given, it was found that *B. coli* were absent from, or present only in very small numbers in, the duodenum, as compared with very large numbers in the concentrated bile. He believed there was a large class of cases of cholecystitis which were curable by medical means—cases in which the cholecystograph was normal, but in which there was some abnormality in the bile. In these cases biliary drainage by magnesium sulphate every morning, olive oil before meals, and large doses of hexamine, with sufficient alkali to prevent the hexamine from being broken up in the bladder and having an irritating action there, was very likely to result in clearing up the condition.

The remainder of the meeting was devoted to the exhibition of cases and photographs bearing on the subject under discussion. These were shown by Mr. T. HOLMES SELLORS (for Mr. MORTIMER WOOLF), Dr. CHARLES NEWMAN, Dr. J. E. A. LYNHAM, and Mr. R. RUTHERFORD, and a number of specimens were lent by St. Bartholomew's Hospital and the Royal College of Surgeons.

NON-TUBERCULOUS PULMONARY FIBROSIS IN CHILDREN

At a meeting of the Society of Medical Officers of Health on April 27th, with the president, Dr. STANLEY BANKS, in the chair, Dr. C. D. AGASSIZ opened a discussion on the relationship of measles and whooping-cough to chronic inflammatory conditions of the chest.

Dr. Agassiz said that since the work of Clarke, Hadley, and Chaplin in 1896 comparatively little further work had been done until recently, but radiological and tuberculin tests had enabled them to diagnose the condition at a much earlier stage. He emphasized the importance of cyanosis as showing the considerable lung involvement that must be present before cyanosis was produced, though the physical signs and x-ray findings might not lead one to suspect the extent of the disease. Cough, dyspnoea, and displacement of organs were the chief symptoms and signs, and he contrasted the latter with those found when the child was suffering from pulmonary

tuberculosis, stressing the variety of the adventitious signs and their inconstant character. In the majority of cases the attacks of bronchitis or bronchopneumonia to which these children were subject were attributable to a previous attack of measles, whooping-cough, or pneumonia. Dr. Agassiz drew attention to the mild febrile attacks to which such patients were liable, and to the concurrent radiographical findings. In his opinion the inflammatory condition in the lungs during these attacks was in the form either of a consolidation affecting the vesicular portions of the lungs or of a peribronchial inflammation.

Dr. G. JESSEL said that intermittent or chronic cough was a frequent complaint among children seen by medical practitioners, and a number of such children were referred by them to tuberculosis officers and seen either at the dispensary or at home. The illness had often been preceded by an attack of measles or whooping-cough, but this was not invariable. In 1933 he had examined 282 children on account of chest symptoms, and eighty-three (29 per cent.) gave a history of measles or whooping-cough: 221 were non-tuberculous, and sixty-three (28 per cent.) of them had a history of measles or whooping-cough. Of the eighty-three who had had these diseases five (6 per cent.) were suffering from pulmonary tuberculosis, and fifteen (18 per cent.) from non-pulmonary tuberculosis—that is, 24 per cent. were found to have tuberculosis in one form or another. Of the 199 children with no history of measles or whooping-cough four (2 per cent.) had pulmonary tuberculosis, and thirty-seven (18.5 per cent.) non-pulmonary tuberculosis—that is, in 20 per cent. there was tuberculosis in one form or another. From these figures, Dr. Jessel concluded that: (1) in children who had had measles or whooping-cough there was a slightly increased incidence of tuberculosis over those who gave no such history, although the difference was not statistically significant; (2) that this slight increase was in the direction of pulmonary tuberculosis; and (3) there was no apparent difference in the frequency of non-pulmonary tuberculosis, whether the child had had measles or whooping-cough or not. He then discussed the radiology of tuberculous and non-tuberculous conditions of the lungs.

Dr. J. E. MCCARTNEY, in introducing the pathological aspect, first outlined briefly the histology of the lung, particularly with reference to the terminal bronchioles. He then dealt with the different types of pneumonia—namely, lobar, lobular or bronchopneumonic, and the interstitial variety. The type of consolidation in measles, he said, was of the interstitial variety, often with obliterative bronchiolitis. Bronchiectasis was caused by a combination of several factors: mechanical, due to inspiration in partially occluded bronchi, and to weakening of muscular and elastic tissue in the bronchial wall; infective, the result of retained secretion; and fibrotic, the sequel of contraction of connective tissue. These various factors combined to produce a vicious circle, with the resultant bronchiectasis and fibrosis met with in later childhood. Dr. McCartney said that these and other sequelae of measles could be avoided if the disease were attenuated by the prophylactic use of human convalescent serum or adult human serum. He advocated widespread publicity for the advantages of attenuating the severity of measles, and said that provision should be made for the extensive employment of adult serum for measles contacts.

Dr. J. S. WESTWATER, commenting on the factors contributing to the development of a respiratory sequel to measles, said he had found it was the younger child who was the more likely to be affected. Equally important, however, was the child's previous history. In a series of cases with lung trouble after measles, 42 per cent. were found to have had a previous respiratory infection. It was possible that minor degrees of vitamin deficiency accounted for the child's susceptibility to pulmonary infection, and it was important to realize that measures directed only towards the prevention and attenuation of acute infections such as measles would be insufficient in preventing chronic lung disease. The prophylaxis of the condition lay as much within the sphere of infant welfare as in fever hospital practice.

Dr. J. N. Dobbin agreed with Dr. Westwater that prophylaxis might largely rest in maternity and child welfare work in preventing avitaminosis of the rachitic type, as well as with Dr. McCartney's suggestion of producing attenuated attacks of the diseases by adult or convalescent serum.

Dr. V. FREEMAN said that, according to Professor Harris, a febrile disturbance such as acute bronchitis or bronchopneumonia interfered with bony growth and left a scar which could be seen radiographically. One might therefore expect that a child subject to repeated acute and subacute exacerbations would suffer considerable interference in its growth and general nutrition, and that growth would certainly be delayed. In a large number of cases he had examined, those suffering from respiratory catarrhs tended to be below normal in height and weight, while the proportion of such catarrhs was very small in those above average weight and height.

The PRESIDENT said that the relatively common disease of pulmonary fibrosis in children of school age was still confused with phthisis, which was a rare disease at this age. At one time the term "pretuberculous" was applied to these children. When sanatorium schemes

were established by local authorities there arose a tendency to drop the prefix in order to obtain sanatorium treatment for the children. With his colleague Dr. J. H. Weir he had investigated one hundred such cases. In 42 per cent. Pirquet and Mantoux tests were negative. Ultimately a diagnosis of chronic pulmonary catarrh or fibrosis, or what might now be termed dry bronchiectasis, was reached in 66 per cent.; the apparent starting-point was severe measles or whooping-cough in sixty and bronchopneumonia in six. The remainder, except one, were also found to be suffering from non-tuberculous conditions, the single exception being a case of pleurisy with effusion. The immediate hope lay in the prevention of severe measles by the widespread use of adult serum by the general practitioner in the case of known contacts under the age of 5 years. The association of severe measles and whooping-cough with malnutrition or avitaminosis, including rickets, required investigation. Healthy, well-nourished children rarely suffered severely from measles or whooping-cough. The ultimate ideal, though doubtless remote, for the prevention of pulmonary fibrosis might be nothing less than the raising of the standard of nutrition of the whole of the infant community.

CORRESPONDENCE

The Method of Medical Care

SIR,—I have just read with great interest the editorial which appears in your issue of April 7th, 1934, page 626, on "The Method of Medical Care" in which reference is made to an abstract of a meeting on the socialization of medicine, recently held in Philadelphia.

In the first column of your editorial you seem to indicate that the Board of Trustees of the American Medical Association and its official staff do not truly voice the opinion of the Association. For this assumption there is not the slightest support. The policies presented by the Secretary of the Association, Dr. Olin West, by myself as Editor, and by the *Journal of the American Medical Association*, which is the official publication of the American Medical Association, are policies officially adopted by the House of Delegates of the American Medical Association which can be found in its proceedings. The House of Delegates of the Association has gone on record officially as opposed to state medicine in all its forms. Until the House of Delegates changes its point of view, the *Journal of the American Medical Association* will continue to present that point of view. Inasmuch as you urge that the *Journal of the American Medical Association* should always present the official view from Great Britain as presented by yourself and your associates in the British Medical Association, it would seem only reasonable to ask that you observe the same courtesy in relationship to the American Medical Association.

It is wholly with a view to avoiding some of the difficulties which admittedly exist in the British scheme of affairs that we have pointed out these weaknesses from time to time. Indeed, you yourself in the last paragraph of your editorial list a number of weaknesses which apparently you have found impossible to overcome.

May I say again that the official policy of the American Medical Association is to welcome experimentation in new forms of medical practice always with the understanding, however, that such experimentation conforms to the principles of medical ethics and does not represent an exploitation of the medical profession by commercial interests or by politicians.—I am, etc.,

Chicago, April 30th.

MORRIS FISHBEIN.

Strangulated Hernia

SIR,—I have read Mr. Wood Power's article (*Journal*, May 5th, p. 787), advocating the use of local analgesia in the treatment of strangulated hernia, with nothing but pleasure. He also advises its use in the operation of "radical cure," quite apart from the complication of strangulation, but apparently limits this advice to patients over 45 years of age. Why? It is certainly quite as good in the case of adults of any age, and I have used it so for many years with altogether admirable results.

As Mr. Power says, the necessity for operation in almost all cases of hernia does not seem to have been sufficiently stressed, and there must be many thousands of people walking about London every day wearing more or less inadequate trusses. Even in the cases where the truss is effective and correctly in place, they do not understand the necessity of wearing some support while in bed and when bathing, and do not realize the care needed to keep the subjacent skin clean and in good nutrition. Cases have come to me with coils of bowel in the scrotum, and the ordinary spring truss pressing more or less over the inguinal canal, with the skin chafed and excoriated. Fortunately the spring had lost its tension long ago, or the result would have been more disastrous still. Mr. Power is unwilling to lay the blame on the general practitioner, and he may or may not be right. At any rate the sale of trusses should be forbidden by law, except on the order of a medical practitioner, and the latter should see the instrument fitted in person, and give full instructions about its use, after fully realizing that he has accepted a grave responsibility in ordering one at all.

When we come to the question of treatment of an apparently strangulated hernia, I am afraid that I cannot altogether agree with Mr. Power on several important points. It is obvious that he dislikes the idea of taxis. Why not be dogmatic, and say straight out that no general practitioner should ever attempt taxis in the patient's home provided a surgeon is within any reasonable call, or a hospital within any reasonable distance? This will clarify the matter at once. Then Mr. Power reluctantly allows himself to put a time factor of safety of four or five hours, while prohibiting the use of taxis altogether in femoral hernias. It is not always easy for a good surgeon to distinguish inguinal from femoral cases in the presence of strangulation, and we have all met with cases where a patch of bowel was more or less necrotic in two or three hours, and an occasional case

where the constricting agent was a band in the hernial sac itself.

But Mr. Power makes his worst mistake in the priority he gives to taxis over the manoeuvre to which he gives only second place after taxis has failed. This is a very bad error. When called to a case which he diagnoses as an *early* strangulated hernia, there is only one piece of advice that should be given to a general practitioner:

Raise the foot of the bed about three feet from the floor by pushing a small table or other object under this end, and apply a partly filled hot-water bag (which should not be too heavy) over the part, carefully interposing some soft woollen material to prevent burns, and ease the weight. Send for a surgeon or a hospital ambulance, and give a small hypodermic injection of morphine.

Even if reduction has apparently taken place before one or the other reaches the house, the patient should go to hospital, where he is under observation, and more time can be given to a really adequate skin preparation. It offers a belated chance of doing a job that should have been done long ago, and no man should be given the chance to endanger his life by delay again.

In treatment Mr. Power advocates the use of the stomach tube when regurgitant vomiting is occurring, with gastric lavage. It may be a quibble, but I prefer to pass the small-calibre duodenal tube, not troubling about lavage, and connect this to a low negative pressure bottle, the patient being kept in a slight Trendelenburg position, and the tube fixed in place as long as there is a regurgitant tendency. In long-standing, badly shocked cases slow infusion of normal saline solution with 0.5 c.cm. of 1 in 1,000 adrenaline solution to each pint should be run into each axillary region from a suspended container while the operation is in progress and for twelve hours after removal to the ward. Mr. Power uses kerocaine 1 per cent. I have always used novocain 0.5 per cent., and find this quite strong enough, but I combine it with 1 in 150,000 adrenaline chloride.

But I think his method of reaching the deep tissues of the cord and the internal ring in the presence of strangulation is horribly dangerous. No doubt he has acquired great skill in the method, but most surgeons will find it much safer and just as efficient to lay bare the external oblique aponeurosis first, clear the pillars of the ring in front, if possible, and pass quite a blunt, short-bevel needle from the external ring region upwards and outwards beneath the aponeurosis, and then inject about 10 c.cm. all down the canal. Mr. Power describes his own method of performing a "radical cure," if necessary combining ablation on the one side. Well, there are many methods, and some of them very good, but any of them will fail unless the aseptic technique is meticulous and adequate relaxation of the parts maintained with properly thought-out support during the first three or four weeks. Old people must be kept propped up, and got into an easy-chair after a few days, or the death rate from pulmonary complications will remain definite.—I am, etc.,

ROY HUCKELL, M.D. Melb., F.R.A.C.S.

London, W 2, May 8th.

SIR,—Mr. R. Wood Power, in his article on strangulated hernia in the *Journal* of May 5th, mentions two methods of non-operative treatment of strangulated hernia—taxis and postural methods. These are discussed as separate lines of treatment. Yet it is possible to combine the two. The patient lies with his buttocks on a pillow on the side opposite to the hernia, the face and shoulders are turned towards the bed, the legs are flexed after a hand is introduced over the swelling in the groin, and taxis is applied. I have found this manoeuvre to be

successful where taxis as ordinarily applied on the supine patient has failed. Perhaps it is the combination of better relaxation of the abdominal muscles and decreased intra-abdominal tension, with the additional pull of the gut ascending in the abdomen, on the strangulated part which brings about the reduction.—I am, etc.,

St. Peter's (Whitechapel) Hospital, May 7th. G. NORMAN CLARK, F.R.C.S.

SIR,—Mr. Wood Power, in his very important article in your issue of May 5th, urges that to prevent strangulated hernia, with its consequent appalling mortality, "There is a way, and only one, by which we can eradicate this mortality; that is a radical cure of the hernia as soon as it appears."

"'Tis a consummation devoutly to be wished," but we are not the only parties in carrying this highly desirable state of affairs into effect. No steps can be taken without the co-operation and consent of our patients, and it is useless to shut our eyes to the fact that there are thousands, if not hundreds of thousands, of men walking about to-day with inguinal hernia, varying from a small bubonocoele to scrotal hernia the size of a foetal head or more, who are fully aware of the danger of strangulation, and yet have not the slightest intention of submitting to a radical cure. No amount of argument seems to convince them. Why? There are two reasons. (1) Many are terrified at the thought of an operation or anaesthetic. (2) Many, possibly the majority, simply cannot afford the time. This applies to medical men, busy city men, and those of the working class alike.

Hitherto there has been only one method of cure of inguinal hernia—namely, by operation, with its attendant loss of valuable time, and, only too often, actual loss of employment. Most of the latter class of patients would be only too glad to be cured if it did not necessitate this more or less lengthy period of incapacity, and many of the former would accept any cure that avoided the dreaded operation or anaesthetic. This is shown by the truly remarkable commercial success of the purveyors of so-called hernia cures, "without trusses," in spite of their obvious futility (vide advertisements in the lay press).

There is a method of radical cure without operation for selected cases, the value of which has been demonstrated conclusively by workers in other countries, especially the United States, where Dr. Ignatz Mayer of Detroit is the leading exponent. This is the injection method of cure of inguinal hernia, which is steadily "growing in favour, though we do not hear of many British practitioners using it" (*Medical Annual*, 1934, p. 227). This method I described two years ago in the *British Medical Journal* (July 2nd, 1932), and it is a remarkable fact that the only opposition to it comes from those who have never seen it carried out, or have only seen one case, and that a failure, and on this they base their judgement. My experience in this method of treatment, since the publication of my article, has only served to confirm the opinion I then expressed, that it is sound and quite safe, and it also has the great economic advantage that it can be carried out without interference with the patient's employment.

It is, of course, only possible to use this method in cases where the hernia is completely reducible, and can be controlled by a steel spring truss, and there must be few completely reducible hernias that cannot be so controlled. I have still to see one. The method has been used by Professor Bratrud of the University of Minnesota for the last four years. He is enthusiastic about it, and tells me that it is well received by the medical profession there. It is also on trial at the Mayo Clinic, although so far only in cases considered quite unsuitable for opera-

tion on account of heart or chest conditions. Cases other than inguinal hernia must, of course, submit to operation. —I am, etc.,

London, W.1, May 11th. **ST. GEORGE B. DELISLE GRAY.**

The Control of Obesity

SIR,—It may be of interest to report a personal experience of Dr. Douthwaite's reducing diet No. 1 (*Journal*, April 21st, p. 701). Commencing on April 21st, when weight in clothes was 13 st. 11 lb., the following is a record of weights day by day: April 22nd, 13 st. 9 lb.; April 23rd, 13 st. 8 lb.; April 24th, 13 st. 7 lb.; April 25th, 13 st. 7 lb.; April 26th, 13 st. 6 lb.; April 27th, 13 st. 4½ lb.—a loss of 6 to 7 lb. in a week. The full rigidity of the diet was relaxed on April 28th, and an addition of a little butter and sugar allowed. The loss of weight was 1 to 2 lb. in seven days, the final weight on May 6th being 13 st. 3 lb.

From the above it will be seen that the diet is remarkably efficient in reducing weight gradually and steadily, but I would hesitate to describe the process as pleasant or the diet as satisfying. Physical lethargy was marked and mental concentration difficult, so obsessed was the mind with the constant thought of food. "The pangs of hunger" was no longer an empty phrase—the sight of such a name as Hungerford was sufficient to intensify the almost constant gnawing and sinking. Sleep was broken and restless; I dreamt of beer though I was not accustomed to drink it. An almost identical record of the sensations of starvation was broadcast recently by one of the survivors of the siege of Kut. Unfortunately, too, I had just read Jack London's epic of starvation, *Love of Life*, and was able to appreciate what surely must have been personal experience.

It is in providing the sensation of satiety that such a diet as Dr. Douthwaite's is so unsatisfactory: meat and fresh fruit are poor substitutes for sugar and fat in this respect, and vegetables are little, if any, better; but the slowing down in the loss of weight since the addition of these constituents is proof that excess of these is essentially the cause of most cases of obesity. Life has worn a rosier aspect since the addition of a little sugar and fat, and it is here that I would disagree with Dr. Douthwaite and contend that it is better to be fat and laugh than to diet and be miserable.—I am, etc.,

London, May 6th.

M.D.

Heredity and Hyperpiesia

SIR,—Hyperpiesia, which is such a common disorder of modern life, has been attributed to a variety of causes: of these, prolonged mental and physical stress has perhaps the greatest support. Other suggested causes are: over-indulgence in food, alcohol, or tobacco; auto-intoxication from teeth, tonsils, accessory nasal sinuses, colon, or genito-urinary tract; gout; and nephritis. That arteriosclerosis and high arterial pressure are symptoms of chronic nephritis is, of course, well known to everyone.

Few, if any, writers have drawn special attention to the factor of heredity. Perhaps most of them have made their deductions mainly from the study of cases seen in hospitals or consulting rooms, the report of whose family history is often vague and uninstructed. Having been engaged in family practice for more than forty years, I have had ample opportunities of examining various members of the same family. Many of these dated from the middle Victorian period, when birth control was practically unknown and large families of ten or a dozen were quite common. As a result of this experience I am convinced that heredity is by far the most important factor in hyperpiesia.

I have seen examples of large families the members of which have been brought up in comfortable circumstances, have led normal healthy lives, without undue mental stress or anxiety or physical strain, and have not over-indulged in food, alcohol, or tobacco—and yet nearly every member, and sometimes every member, who reached the age of 50 or upwards has died of cerebral haemorrhage or myocardial degeneration the result of high blood pressure. To quote one instance only of hereditary transmission in a smaller family.

Two brothers, A and B, who were married, died of "apoplexy" at the ages of 55 and 68 respectively. A, who was considerably the older, left two sons and two daughters (the wife died from another cause when the youngest daughter was a few years old). One of the sons has since died of cerebral haemorrhage at a little over 50; the other son and elder daughter both suffer from hyperpiesia; the younger daughter (who resembles the mother) has normal blood pressure. B's wife died of phthisis, leaving one son and three daughters. The three daughters died of pulmonary tubercle as young women. The son (who resembled the father) died of cerebral haemorrhage at 50. His blood pressure had been abnormally high for several years.

On the other hand, I have known other large families some members of which have had exceptional mental stress and worry, and others who have had considerable physical strain—and all of them have had practically normal blood pressure throughout their lives.

Alcohol is often considered to be a contributory cause. It is difficult to see what grounds there are for this: alcohol is a vaso-dilator. The first symptom of a slight overdose is usually flushing of the face. I have hardly ever seen chronic alcoholic addicts with high blood pressure; generally it is notably subnormal. Hyperpiesia appears to be decidedly more common among total abstainers or very moderate drinkers than among alcoholics.—I am, etc.,

HERBERT H. BROWN, M.D., F.R.C.S.

Worthing, May 7th.

Epidemiology of Influenza

SIR,—In your issue of March 24th (p. 556) Dr. Howard Wise refers to the paper of Dr. Torrens (February 17th), and attempts to associate the periodic invasions of Europe and other parts by influenza with the periodic silting up and overflowing of a certain large river in Asia. Now, to bring up a theory such as Dr. Wise has done the facts on which he bases his argument must be correct, otherwise his whole argument falls to pieces.

Dr. Wise suggests that in the pandemic of 1918 the usual route of invasion was closed on account of the privations of war, and that it arrived in Europe "via the Cape," making its first appearance in Spain—hence the term "Spanish influenza." As one who has been practising in the Cape for many years, and who was in Capetown during the epidemic, I am able to write with a first-hand knowledge of the epidemic as it affected this part of the world.

For some weeks before a single case was seen in Capetown we knew of "Spanish flu" by means of the daily papers, and tried, as far as we knew how, to prepare for it. (Any preparation we made was utterly useless.) The first cases, curiously enough, appeared in Johannesburg, where the occupants of a mine compound suddenly succumbed. This invasion was later traced to a boat which had arrived in Capetown from Europe, but the infection had missed Capetown and gone straight to Johannesburg, appearing a few days later in Capetown. The first authentic case that I saw was about September 27th, long after the epidemic was raging in Europe. After this date the deluge came, and I believe that the Cape Peninsula suffered more severely in this epidemic than

any part of the world, except some parts of India. "Black October" is still very well remembered in this peninsula. The invasion of Central Africa (Nyasaland, Kenya, Uganda) came later than in South Africa, and only when things were beginning to quieten down here.

Dr. Wise is incorrect when he states that "the disease was spreading in South and West Africa before it reached Europe." The reverse is, however, true. South Africa received its infection direct from Europe, and in its turn passed on the disease to other parts of the continent. As the epidemic of 1918 definitely did not arrive in Europe by way of the Cape, and as the ordinary routes of invasion from Asia were closed, according to Dr. Wise, because of the war, it seems possible that "Spanish flu" originated in Spain! On the other hand, I am not at all convinced that the war was a barrier to invasion. Rather would I credit the war and war conditions with easing the way for a direct spread of infection from one country or continent to another, and therefore, if the epidemic were of Asiatic origin, all conditions were at that time favourable for a world-wide spread.—I am, etc.,

Capetown, April 19th.

EDWARD E. WOOD.

Silicosis and South Wales Colliers

SIR,—As a radiologist practising in the South Wales coalfield, it would seem to me that a few observations on this important subject would not be out of place at this juncture. Discussion has been fast and furious as to the causative agent, to the findings of the boards, and to the great prevalence of the disease among the miners of this area.

From my standpoint it matters little whether the cause of the condition be silica or sericite, so long as there is a definite increase of fibrous tissue formation in the lungs. Further, there seems to be little mystery why there are so many cases of silicosis in this part of South Wales when the full facts are known. Among the coal miners it is the custom to have deductions made at the colliery offices on behalf of the medical men in the district. This has many advantages, and also many disadvantages, both for the doctor and for the mine worker. One of the advantages, so far as I am concerned, is that the workmen can have a roentgenological examination if the family doctor is doubtful of the patient's condition. Silicosis is the fashionable disease in this area at present. The result is that a great many men have been examined, and that a more or less systematic examination (x-ray) has been made of those men who have worked in the mines for several years.

It is probably safe to state that more colliery workmen have been x-rayed in this area than in any other part of the coalfield; hence more cases of silicosis have been found than in any other areas where no such examination has been carried out. This, it would seem, is part of the reason why there are many more known cases in this area than in any other part of the country. What the results of similar examinations would yield as regards silicosis in the other coalfields it is impossible to state until such examinations are carried out.

All that can be said is that there would appear to be more cases in South Wales than in the other parts of the coalfields. The returns of the Registrar-General need not of necessity be very accurate. Professor Kettle (*British Medical Journal*, February 10th, 1934, p. 254) states that the specimens sent to him were nearly always those of infective silicosis, and the infecting organism was most commonly the tubercle bacillus. This statement is much more reliable than any returns of the Registrar-General. There would therefore seem to be no difference between the silicosis found in South Wales and the type

of silicosis as commonly accepted. I can find no roentgenological difference between cases of silicosis in South Wales and cases seen by me in the Belgian coalfields. Further, as soon as the silicotic receives his compensation all interest is lost in his case until his death and post-mortem examination. The results of the examination show the cases to be typical of pneumoconiosis.

Unfortunately I did not keep an accurate record of all the cases examined by me during the past year, as my findings are sent on to the local medical men. I can, however, trace some fifty-eight patients, all of whom are suffering from pneumoconiosis in one stage or another. Some of the number refused to be examined by the board, as partial compensation of about £1 per week is a very inadequate sum to meet the necessities of life. These men prefer to continue at work regardless of the cost to their health, as they refuse to be compulsorily retired with partial compensation and no further hope of any employment. There are therefore more cases of silicosis than have been either examined or passed by the board.

A few notes on the fifty-eight cases would probably be of interest. For my own purposes the stages of the disease were divided into three as follows: first stage, five cases; second stage, twelve cases; third stage, forty-one cases.

First Stage.—Roentgenologically, this stage shows an increase in the prominence of the hilum shadows, with some slight haze and very fine lines containing fine granular deposits. This condition is, as a rule, confined to the right lung field. (Patients were advised to continue at their ordinary work.)

Second Stage.—This stage naturally falls into three subdivisions: (a) early, (b) medium, and (c) late. This is the commonest stage seen, and is characterized by a definite distribution of small opacities, somewhat rounded, varying in sizes and densities. These opacities are at first seen in the hilar region of the right lung field; they spread outwards and downwards in a fan-shaped manner; the condition spreads to the left lung, and a typical picture of the disease is one, in which both lung fields are occupied by numerous irregular granular deposits—more extensive in the right lung field than in the left lung field—with a fine network-like arrangement of fibrous tissue. This network gives rise to numerous pseudo-cavities. (Some of these patients continued at work; others were advised, on account of their shortness of breath, age, etc., to be examined by the board. Some had full compensation, while others obtained partial compensation.) The findings of the board were in my opinion all that had been anticipated, with the exception of one case. This man received partial compensation only: I should have awarded him full compensation.

Third Stage.—(a) Medium, and (b) advanced. In this stage the larger granular opacities begin to fuse into large irregular masses, best seen in the region of the hilum, and as a rule more marked in the right lung than in the left lung. The process continues until two or three masses may be seen in the right lung field, and one or two in the left lung field. The diaphragm is definitely flattened, irregular, and shows sharp peaks. Although these large opacities are to be found as a rule in the hilar area, they are occasionally found subapically. Finally, the opacities occupy the larger part of both lung fields. (All these cases have been examined by the board.)

Differential Diagnosis.—This is from pulmonary tuberculosis. In silicosis both lung fields are affected almost to the same degree—the right a little more than the left. The condition principally affects the middle and inferior parts of the lung fields. The distribution, size, and form of the individual spots are more even, while there is a deformity of the diaphragm. The granular deposits are denser, and are connected together by a fine network-like arrangement of fibrous tissue, giving coniotic lung a definite lacework-like appearance with numerous pseudo-cavities. There is also the marked difference between the roentgenological findings and the physical condition of the patient, whose only complaint is shortness of breath on exertion, while any haemoptysis is, as a rule, transient and inconsiderable.

In the cases under consideration (late second and third stages) all the men have received compensation. Their

ages vary from 36 to 64 years, and the men have been engaged in the mining industry from twenty to thirty-eight years. Two were engaged as colliers for some two years, and then became shot-firemen. Several stated that they had never worked in a "hard-heading." Their family histories were good—no relatives were, or are, suffering from tuberculosis. With the exception of one, who had several years previously suffered from pneumonia, all were free from any chest complaint up to one year previous to the roentgenological examination. In only one family were two members suffering from silicosis; while in another instance, of two men who had been working across each other for several years, one showed advanced disease while the other showed no evidence of any disease.—I am, etc.,

Centre, University of Liège.

Ammanford, Wales, April 30th.

The Tuberculosis Problem: Canadian Experience

SIR,—I have been much interested during the past few months in letters written on the tuberculosis problem, especially that of Dr. F. R. Waldron. May I submit the following with reference to the campaign for the prevention of tuberculosis among our school children, and its results in the city of Fort William, Ontario?

Our city has a very cosmopolitan population of about 25,000. The public school attendance (ages 5 to 15 years) is about 4,000; the secondary school attendance (ages 15 to 20 years) is 1,800. The problem of prevention of tuberculosis among school children first came prominently before the Board of Education about three years ago, when one of our teachers was a victim of this disease and one of our high school pupils succumbed soon after graduation. As the milk of our city is all pasteurized before being consumed bovine and bone tuberculosis are unknown. We therefore centralized our efforts on the prevention of tuberculosis of the lungs.

May I state at the outset that our school teachers and other employees undergo a yearly medical examination. A set form is supplied for this purpose, having special reference to tuberculosis of the lungs. For health purposes our schools are divided into three zones, supervised by three school nurses working in conjunction with the medical health officer and under the direction of the Board of Education. Illustrated lectures on the prevention of tuberculosis have been given by both local doctors and school nurses at the schools. Radio addresses have also been given and printed matter distributed. All our public school children have been examined, and suggestive signs of incipient tuberculosis reported to the parents. Contacts and suspects have been tabulated and the intracutaneous skin test given. Positive reactors have been noted, watched, and advised. If deemed necessary, x-ray photographs have been taken by a specialist, the plates interpreted, and reports given at a minimum cost. For parents unable to afford this service the fee is provided by a local charity, any positive reports being sent to the family doctor or the medical health officer. To date, about 600 have been given the tuberculin skin test, about 5 per cent. showing a positive reaction. Forty-five x-ray photographs have been taken, of which three contacts showed incipient tuberculosis. These were given suitable treatment and excused school for six months. They are now restored to perfect health.

Our experience shows (1) that the Mantoux test is reliable; (2) that it is not necessary to have such a high percentage of x-ray plates taken; (3) that infected tonsils and adenoids, enlarged heart, or quiescent fluid or pus in the lungs may be mistaken for tuberculosis; and (4) that we are getting fewer positive tuberculin tests, and that

tuberculosis of the lungs is now a rarity. Further, skin reactors should be carefully watched and building-up treatment advised. If there is any loss of weight, or should the child become easily fatigued, an x-ray examination of the chest should be recommended. Through our efforts the community has become tuberculosis conscious. Adults are consulting their physicians more frequently, and cases are becoming diagnosed earlier and therefore more easily cured. We are hopeful that the time is not far distant when tuberculosis of the lungs will be entirely eradicated.—I am, etc.,

Fort William, Ontario, Canada. B. C. HARDIMAN, M.D.
April 17th.

The Cancer Problem

SIR,—It does not seem likely that Dr. Cramer, in his reference to the review of Mr. Lockhart-Mummery's and my own books on the cancer problem, would have denied so emphatically that cancer increases with civilization unless he has given the subject serious consideration and is prepared with evidence more definite than that which he mentioned.

1. He surely accepts the view commonly accepted that among human beings cancer seldom makes its appearance until middle age or afterwards. According to Sir George Newman the proportion of those who live to 55 years or over has risen from 10.6 per cent. in 1900 to 15.3 per cent. in 1929, or nearly 50 per cent. Nor is it possible to attribute this increase to anything but improvements in our methods of civilization. Can Dr. Cramer say how this advancement in age and in civilization can be reconciled with his statement that cancer is not also increasing?

2. In attributing the rise in the death rate from cancer to improved methods of diagnosis does Dr. Cramer take into consideration not only those instances in which death from cancer was formerly put down to other causes, but also those which at one time would have been wrongly certified as cancer?

3. Then again, increase in cancer *deaths* is not the same as increase in cancer, for many more cancers are now eradicated than was the case thirty years ago. Hence it seems by no means unlikely that those saved from death by modern treatment more than balance those additions to the death statistics which are due to modern improvements in diagnosis. Cancer may be increasing in prevalence year by year while the death rate from cancer is stationary or diminishing.

4. Advancement in material civilization implies the invention of an ever-increasing number of appliances, some of which—for example, tar products, x-rays, radium, dentures, tobacco, alcohol, arsenic—are carcinogenic. Another cause of cancer—syphilization—is also notoriously a product of civilization. Can Dr. Cramer explain how it is that the increase of these exciting causes of cancer in a civilized community is not attended by an increase in cancer? This anomaly can hardly be due to a decreased resistance to cancer-producing agents on the part of the civilized, for the testimony of various authorities, medical and lay, seems decidedly to favour the view that savages are more and not less resistant to the cancer-producing effects of stimuli.

Among much other but more controversial evidence in favour of the view that cancer is rapidly becoming more prevalent are some recent figures collected from the records of the post-mortem room at Guy's Hospital.¹ These tend to show that whereas from 1904 to 1913 the average yearly figures were sixty-nine cancers of various types, from 1924 to 1933 the number had risen to a yearly average of 102; or an increase from 10.7 per cent. to 19 per cent. of post-mortems.—I am, etc.,

Reading, May 14th.

HASTINGS GILFORD.

¹ Guy's Hospital Gazette, April 28th, 1934, p. 193.

SIR,—In the review of my book *The Origin of Cancer*, which appeared in your issue of May 5th, your reviewer starts with the statement: "The fact that cancer is much more frequent among civilized than savage races," etc., "is one of the outstanding features of the disease." It might reasonably be inferred by anyone reading the review that I had expressed such an opinion in the book, whereas my opinion is the exact opposite. The actual statement in the book is: "It seems at least reasonable to conclude that were it possible to collect equally reliable data from all parts of the world, the statistics would show that after making proper allowances for the number of individuals living per 1,000 at a given age, etc., the cancer incidence varies very little geographically or racially." I notice that Dr. Cramer has in to-day's issue drawn attention to this matter, but I should like to make it quite plain that I had expressed no such view in my book.

I am much interested in Dr. Harry Campbell's criticism of one of the views expressed in my book—namely, "that man and his domestic animals have not been subject to the law of natural selection for thousands of years." I had not meant to suggest that the elimination of the unfit had entirely stopped, but that the process had been so seriously interfered with that the unfit were no longer entirely eliminated or prevented from passing on their unfit characters to succeeding generations. We have very strong evidence of this in the number of persons exhibiting hereditary defects at the present day, such as cleft palate, hereditary blindness, mental deficiency, haemophilia, deaf-mutism, etc. One can hardly doubt that if natural selection had been acting in the natural way such defects would have been quickly eliminated, instead of which the number of persons exhibiting such defects is increasing. Where natural selection has full sway only perfect individuals would have any real chance of survival, the rest being quickly eliminated. The individual members of any family of wild animals show very little variation either in appearance, ability, or character. Modern civilization tends to preserve individuals with hereditary defects, and allow them to pass on their mutated genes to succeeding generations in ever-increasing numbers. When man began to civilize himself and his domestic animals he put a bolt in the machinery, which prevented it from functioning properly, and unless he can find a way out by other means he must inevitably pay the price of his interference.—I am, etc.,

London, W.1, May 12th. J. P. LOCKHART-MUMMERY.

** There was no suggestion in the review that either Mr. Lockhart-Mummery or Mr. Hastings Gilford was responsible for the opening statement.—Ed., *B.M.J.*

Poisoning by Ground Ivy

SIR,—I think the case mentioned by Dr. Aitchison Robertson (May 12th, p. 872) must have been one of idiosyncrasy. I have handled this plant for many years, and so have the men employed in my garden, with no harmful results, nor have I been able to come across any such cases. But I have found an infusion of the bruised herb of the greatest value in the treatment of that particularly distressing prurigo that often accompanies the later stages of cancer, especially the abdominal forms. I got the idea from a country girl, servant to a well-known London practitioner. He was kept awake by the itching; there was no rash. She said that in her part of Kent an infusion was used to allay this sort of trouble. We got some, made an infusion with boiling water—two handfuls of the herb, well bruised, to the pint. The result was relief, good sleep, and a grateful patient. Another case in a consulting surgeon to one of our leading hospitals had the same excellent result. Our country folk used to

dry the plant and make tea with it. It was used in the acute ophthalmia in horses resulting from injury. A leaf was put under the lid, and the carters said it was a good remedy. About this latter idea I "hae ma doots," but of the former I am sure.—I am, etc.,

F. WILLIAM COCK, M.D., F.S.A.
Appledore, Kent, May 13th.

Maternal Mortality

SIR,—Some weeks ago a popular daily paper published an article entitled "Maternal Mortality" by a "Famous Gynaecologist." This article aroused a good deal of interest in both medical and lay circles at the time. Having read the contribution in question, to me one fact seemed very obvious—namely, that the famous gynaecologist was simply quoting from textbook writing on the subject. The suggestions made in the publication were the well-worn ones, familiar to every student of public health, and incorporated in the Maternity and Child Welfare Act, 1918. It is interesting, therefore, to see what influence the adoption of the above Act has had during the past fifteen years on the maternal mortality rate.

In 1918 the maternal mortality rate was 3.79; in 1933 the rate was 4.32. It follows that in so far as the Act is a measure to reduce maternal mortality it has failed. It seems to me that the subject must be approached on different lines if any headway in reducing deaths in confinement is to be made.

It must be obvious to all medical men that no amount of improved training in midwifery, for students, nurses, etc., and no amount of increased theoretical knowledge, will help towards reducing maternal mortality so long as midwifery is practised as it is at present (that is, as practised by the majority of general practitioners). The general practitioner is fully aware of the dangers associated with interference at a confinement, but in order to keep his practice he must placate the midwife and the patient's friends, and so he often interferes without adequate assistance, and before the conditions for interference are fulfilled. As a general practitioner, I believe the adoption of the following scheme would reduce maternal mortality.

1. Compulsory notification of pregnancy and a fee for such notification.

2. The practitioner, when notifying the pregnancy, to indicate whether he is willing to be responsible for the confinement or wishes the local authority to be responsible.

3. By such a selection the doctor can retain those patients who are able to pay him a composite fee to cover ante-natal care, etc., while he can pass on to the local authority those patients unable to pay such fee.

4. Local authorities to provide whole-time medical officers for the care and delivery of expectant mothers so referred to them.

5. Local authorities to circularize all notified cases concerning (a) health in pregnancy, (b) the desirability of allowing the doctor to choose the midwife, (c) the importance of being patient in labour and of leaving the conduct of the confinement to the doctor's decision.

6. Such circularization will do much to stop the craze for hasty delivery—which, usually, implies bad midwifery.

7. It is important that the doctor should choose the midwife; in this way the meddlesome and impatient midwife will be driven out of active practice. At present, in most places, the midwife chooses the doctor, and in order to conserve her energy she, frequently, has schooled her clientele to expect the doctor to be a man of magic.

8. At the end of each year every doctor practising midwifery to make and send to the local authority a statistical table showing (a) the number of confinements conducted, (b) morbidity rates, (c) deaths, if any, and causes of same.

9. Comparison of such tables with records of cases conducted by the local authority. Such a comparison would be very informative. Presumably, the local authority would

appoint only medical officers with special midwifery experience, and it would be interesting to compare their results, when working in poor homes and under difficult conditions, with those of the less specialized general practitioners, working in somewhat better home conditions.

In this way a healthy competitive spirit to secure good results would be engendered among medical men. They would therefore hesitate to act hastily, nature would conduct most of the confinements, interference would be reduced to a minimum, and, as a result, sepsis would be largely eliminated and so the maternal mortality rate would fall.

It is my belief that a definite drop in the maternal mortality rate would follow (1) legislation on the above lines, and (2) its immediate and compulsory adoption by medical men.—I am, etc.,

JAMES G. DEVLIN, M.B., D.P.H.

Handsworth, Birmingham, April 25th.

Osteopathy

SIR,—Sir Ernest Graham-Little has reminded us that the Osteopaths Registration Bill is now before Parliament, and I think that medical men at least should be acquainted with the truth about this movement. "In the first place, osteopathy has nothing whatever to do with "bone-setting," or with manipulative surgery, or the therapeutic manipulation of stiff joints. Manipulative surgery is now a recognized branch of orthodox surgical practice based upon sound pathological principles.

Osteopathy was started little more than fifty years ago by a certain Dr. A. T. Still of Chicago, who enunciated the principle that "the law of the artery is supreme," and taught that practically all diseases are due to pressure upon the blood vessels in the intervertebral foramina, brought about by (imaginary) displacements or "lesions" of the vertebrae. About twenty years later a man named Palmer of Davenport, Iowa, announced that he had made the "discovery" that 95 per cent. of all diseases are due to pressure upon the nerves in the intervertebral foramina, brought about by the same (imaginary) displacements of the vertebrae. He enunciated the principle that "the law of the nerve is supreme," and he founded a school of chiropractic in opposition to the school of osteopathy previously founded by Still. The essence of both these doctrines is the treatment of remote diseases by the manipulation or "adjustment" of the imaginary spinal lesions which are supposed to be their cause. These rival factions (to mention only two) have flourished exceedingly in the United States of America. But they have almost exhausted the field of credulity in that remarkable country, and they are now making the most strenuous efforts to secure a status which would enable them the better to exploit the resources of this country. It should be clearly understood that this is an American stunt; the British element in osteopathy is practically negligible.

Enough has been said to show that these factions are not agreed among themselves as to which particular "theory" shall be put across the public as a cloak for empirical manipulation of the spine, and it will be interesting to see whether our enlightened legislators decide to give their official blessing to "the law of the artery" or to "the law of the nerve," or to all and sundry of these quick manipulators. It has been naïvely suggested that osteopaths do not require the full training of the medical curriculum to fit them for the practice of their art. One answer to this is that the last *Osteopathic Journal* that came into my hands was concerned entirely with the treatment of cancer of the uterus!—I am, etc.,

London, W.1, May 7th.

Obituary

ALFRED RICHARDSON, M.B., B.S., F.R.C.S.
Honorary Surgeon, General Infirmary at Leeds; Professor of
Clinical Surgery, University of Leeds

The death, at the age of 49, of Mr. Alfred Richardson occurred with tragic suddenness on April 22nd as the sequel to an attack of coronary thrombosis on April 13th. The General Infirmary and the Leeds School of Medicine have been hard hit during the last fifteen months, for within that space of time they have lost three members of the active staff and three of the consulting staff.

Educated at Epsom and trained at the Leeds School of Medicine, Richardson graduated M.B., B.S. Lond. in 1907, with distinction in pharmacology and honours in medicine. He held in succession the appointments of house-surgeon, resident casualty officer, and resident surgical officer at the Infirmary, and subsequently that of surgical tutor and registrar. In 1910 he obtained the Fellowship of the Royal College of Surgeons of England. During the war he served with the 2nd Northern General Hospital at Beckett Park, Leeds, and for a period with a general hospital in France. In 1920 he was elected honorary assistant surgeon to the General Infirmary, and became surgeon in 1927. He quickly made for himself a reputation as a skilful operator, a sound diagnostician, and a clear and capable teacher. In his operative work he combined a perfect and delicate technique with a rare judgement, which enabled him to carry through, with safety and success, operations often of great difficulty. His chief concern was always the welfare of his patient and to plan that particular line of treatment which would be best for the individual case. These qualities earned for him the admiration and confidence of his fellow practitioners and a large and increasing practice. After holding the appointment of honorary demonstrator in surgical pathology he was, in October last, elected to the chair of clinical surgery, and the enthusiasm with which he discharged his duties made it clear that a very valuable addition had been made to the staff of the University. In addition to his Infirmary appointment Richardson was consulting surgeon to several of the small hospitals in the neighbourhood, including the Ilkley Coronation Hospital and the Ministry of Pensions Hospital. For this last appointment no better man could be imagined: his cheery, forceful personality, combined with his kindness and great technical skill, were just the qualities to appeal to the ex-service man, and the large attendance of these men at his funeral was evidence of the affection and esteem with which they regarded him.

An athlete in his younger days, he was always intensely virile and alive, and among students a popular and stimulating personality. His method of teaching was simple, clear, and concise, punctuated with witty and sometimes caustic comments which effectively brought home the points he wished to make. Not suffering fools gladly, he nevertheless was full of the milk of human kindness, and enjoyed the confidence and affection of everyone connected with the hospital.

His death at a time when it appeared that an increasingly successful career as a surgeon and a teacher was before him means a loss to the profession and the Leeds School of Medicine which it is difficult to estimate.

H. C.

THE LATE PROFESSOR WELCH

Through the courtesy of Colonel Fielding H. Garrison we have received extracts from the *Baltimore Sun* of May 1st, a large part of which was devoted to the career of Professor William H. Welch, of whom a memoir by Sir Humphry Rolleston appeared in our last issue at page 874.

A leading article in the *Sun* pays high tribute to the part played by Welch in the advance of American medicine, and adds:

"Baltimore, where Dr. Welch lived and worked, must not be allowed to forget that the man was, from his arrival here as a young man to the end of his life, an explorer, a scholar who challenged, every time he met it, the tendency to 'believe nothing so firmly as that which we least know.' That he did it with a gentle urbanity did not weaken his attack. Those who opposed Dr. Welch in his early fight for public health work here in Baltimore knew they had been in a fight. The epicure, the lover of books and plays and talk, the homely philosopher—all merged into Welch the scientist, tireless in the search for truth and restless in its propaganda. Should this be ignored, and this amazing career be passed over in favour of amusing anecdotes about Dr. Welch's attitude on woman suffrage or the long cigars he smoked, then we could say that Dr. Welch was dead. But the world of science and achievement will place a true and lasting estimate upon Dr. Welch, knowing that, above and beyond the gracious memories of kindness and wit and worldly wisdom, there was the great man."

THE LATE DR. CAMPBELL McCLURE

Dr. TEMPLE GREY writes: "Médecine can ill afford to lose such men as Campbell McClure. Big in mind and big in body, narrowness of vision and pettiness alike were strangers to him. It is a tragedy that, in the nature of things men who have seen and done so much should have so little time to write for our instruction. One of the dwindling body of true clinicians, he could have written as few others on common sense in medicine. He saw his patient as a whole, and was able to bring to bear upon his case a true erudition culled rather from experience and observation than from books. It was little satisfaction to him to be "right" in his diagnosis unless he could relieve his patient. High-sounding diagnoses made little appeal to him, nor did fussy therapeutics enchant him. Large numbers of patients to whom he brought comfort and relief, and friends who valued his friendship, will miss him badly."

The death took place at his residence, St. Catherine's, Linlithgow, on May 9th, of Dr. JAMES HUNTER, one of the best-known practitioners in West Lothian. Dr. Hunter was born at Dumfries in 1856, and after a medical course at Edinburgh University graduated M.B., C.M. in 1878, proceeding M.D. with honours in 1887. After a period of study in Vienna, Dr. Hunter went to Linlithgow as assistant to his uncle, the late Dr. George Hunter, and subsequently was in practice in South Queensferry at the time when the Forth Bridge was being built. Later he took over his uncle's practice in Linlithgow, where he continued for fifty years. He identified himself with local public affairs, serving on the town council for nine years, and as J.P. for the county of West Lothian. In 1929, in recognition of his fifty years' service to the community, Dr. Hunter was presented with his portrait. He was a brother of Dr. Joseph Hunter, Member of Parliament for Dumfries, and is survived by a widow and family, of whom one son and three daughters are members of the medical profession.

We regret to announce the death of Dr. JAMES KIRK, on May 3rd. Dr. Kirk, who was in his sixty-seventh year, had only within the last twelve months relinquished practice in Bridlington to take up work in North London. After winning the Grierson bursary in pathology and materia medica, he graduated M.B., C.M. at the University of Edinburgh in 1895, obtaining the M.D. two years later. In the meantime he had made a special study of ophthalmology. He joined the Colonial Medical Service, being stationed for many years in Penang, where he acted as ophthalmic surgeon to the Government hospitals, and was physician to the King Edward VII Hospital for Women and Children; he was also, at one time, surgeon to Singapore General Hospital, held the rank of major, and was officer commanding the Ambulance Company of the Penang Volunteers. At the outbreak of the Great War he came home and at once obtained a temporary com-

mission in the R.A.M.C., serving as ophthalmic specialist at the Curragh and in Malta. At the conclusion of hostilities Dr. Kirk entered into general practice at Bridlington, where he remained till the middle of last year: he held appointments as ophthalmic surgeon to the Education Committee and to the Lloyd Hospital. He was a member of the North of England Ophthalmological Society, a Fellow of the Royal Society of Tropical Medicine and Hygiene, and had been a member of the British Medical Association since 1898. Dr. Kirk was of a quiet, retiring disposition, never seeking to be in the limelight, fond of country walks, his dog, and a pipe by his own fireside. Behind a somewhat aloof manner was hidden a genial and kindly nature, and his colleagues knew him to be incapable of any mean thought or petty action. He is survived by a widow, two daughters, and a son.

The sudden death of Dr. DAVID FALCONER RIDDELL, came as a shock to Woolwich and its neighbourhood, where he was very well known. Born in Glasgow in 1878, he was educated at the High School, where he obtained the Lumsden gold medal, and at the University of Glasgow. He took his degree in Arts in 1897, and in 1903 graduated M.B., Ch.B., and in 1907 obtained his D.P.H. at Cambridge. After holding house appointments in the Glasgow Royal Infirmary and Ruchill Hospital he entered the service of the Metropolitan Asylums Board, and was a senior assistant medical officer when he resigned, in 1919, to take up general practice in Woolwich. When the war broke out he became medical officer in charge of the Belgian Dispensary (Sheffield Street, London) until 1916, and for his work there he received King Albert's Medal. Thereafter, as an officer in the R.A.M.C., he served with distinction, and was awarded the Military Cross in 1918. For many years Dr. Riddell was the secretary of the School Treatment Committee in Woolwich, and was a past chairman of the Woolwich Division of the British Medical Association. He leaves behind a widow, and a son and daughter. His name and record of service will not soon be forgotten, and his fine qualities will be warmly cherished by a wide circle of colleagues, patients, and friends.

We regret to record the death of Dr. HUGH JONES of Dolgelly, at the age of 70. Dr. Jones graduated M.B., C.M. (with commendation) at the University of Glasgow in 1888, and in the following year received the D.P.H. He had been a member of the British Medical Association for forty-four years, and was a member of the Insurance Acts Committee from 1919 to 1921, and the Rural Practitioners Subcommittee from 1920 to 1922; he also served on the British Medical Association's Ministry of Health Committee during 1920 and 1921, and had been president of the North Wales Branch of the Association. Among his medical appointments were those of senior house-physician, Western Infirmary, Glasgow; house-surgeon, Glasgow Maternity Hospital and Glasgow Lock Hospital; medical officer of the Endowed High School for Girls, Dolgelly; lecturer and examiner of the St. John Ambulance Association; medical officer of health for the Dolgelly Rural and Urban District Councils; public vaccinator for the Dolgelly District; and medical referee for the Prudential Assurance Company. Dr. Jones was an honorary member (late president) of the Glasgow University Medico-Chirurgical Society. He was a justice of the peace for the county of Merioneth.

The May issue of the *Canadian Medical Association Journal* contains a full memoir, with portrait, of Professor Archibald Byron Macallum, M.D., F.R.S., whose death was announced in these columns on April 14th. "In him," our contemporary says, "Canada loses one of the most distinguished scientists she ever produced, a man outstanding all over the world in the field of biochemistry. His great achievements were never spectacular, but among the scientists of the nations he was recognized as a leader."

ROYAL MEDICAL BENEVOLENT FUND

During the first quarter of this year £3,674 has been voted in grants, as against £3,489 during the corresponding period of last year. The increasing number of cases and the necessity of helping the many applicants who are known to be deserving and in great financial difficulties render the appeal for the support of the Fund the more urgent. Cheques should be made payable to the Honorary Treasurer, Royal Medical Benevolent Fund, 11, Chandos Street, Cavendish Square, W.1.

The following are particulars of a few cases recently helped:

M.B., Ch.B., aged 47, married, daughter aged 10. On leaving the Army after the war the applicant had no practice to return to; and, having developed disseminated sclerosis, he was not capable of undertaking the medical work of an arduous practice. A county council in 1920 appointed him medical officer, in which post he made a great effort to carry on. His condition did not improve, and finally he had to resign in 1933. Income, pension £100, wife's private income £20. Fund voted £40 in four instalments for a period of one year.

Widow, aged 32, of M.B., Ch.B. The husband served abroad, and died recently from tuberculosis at the age of 33, leaving the widow and two children—boy aged 7, girl 5. The widow is entitled to a pension of £60 and allowances for children £45. A life policy, when invested, will yield £35. Total income £140. No relations can help. Fund granted £26 in four instalments over a period of one year.

Daughter, aged 69, of M.R.C.S. The applicant has been working for her living for over thirty years. She and a cousin ran a boarding house up to two years ago, when they had to give up owing to local competition. They moved to a smaller house with a view to taking lodgers. Only a little money is now earned. The cousin has the old age pension of £26, but the applicant is not eligible for that till next year. Fund granted £26 in four instalments over a period of one year, and is endeavouring to get other assistance for these two ladies.

Universities and Colleges

UNIVERSITY OF OXFORD

On the evening of May 3rd an audience of over 200, including many eminent people in university and city life, attended a demonstration of x-ray cinematograph films, given in the large Lecture Theatre of the University Museum by Dr. Russell J. Reynolds of London and Dr. Robert Janker of Bonn, two of the pioneers of this branch of medical science.

The examination for the Diploma in Ophthalmology will be held on Monday, June 18th. Names must be entered by 10.30 a.m. on Thursday, May 31st.

The following nomination has been duly received by the Registrar: As a member of the General Medical Council of the United Kingdom, Sir E. Farquhar Buzzard, Bart., D.M., Student of Christ Church. Nominated by K. J. Franklin, D.M., Fellow of Oriel College and Dean of the Medical School, and E. W. Ainley Walker, D.Sc., D.M., Fellow of University College.

UNIVERSITY OF CAMBRIDGE

At a congregation held on May 11th the following medical degrees were conferred:

M.B.—R. W. Billington, M. Westwood.

UNIVERSITY OF LONDON

The following appointments to the Senate for the period 1934-8 are announced: Faculty of Medicine, Mr. H. L. Eason, M.D., M.S. (reappointed), and Dr. A. M. H. Gray; General Medical Schools, Mr. W. Gurling Ball, F.R.C.S.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

A meeting of the Council of the Royal College of Surgeons of England was held on May 10th, when the President, Sir Holburt Waring, was in the chair.

Diplomas of Membership were granted to A. J. W. Branch and V. P. Gupta, and to 164 other candidates who had passed the Final Examination in Medicine, Surgery, and Midwifery of the Examining Board in England, and whose names were printed in the report of the meeting of the Royal College of Physicians of London in our issue of May 5th (p. 827).

The Diploma in Gynaecology and Obstetrics was granted, jointly with the Royal College of Physicians, to K. S. Jayakar. Mr. C. A. Pannett was re-elected a member of the Court of Examiners.

Mr. Laurence O'Shaughnessy was reappointed College Research Scholar from June 24th to September 29th, and Mr. G. C. Knight and Mr. G. Slome were reappointed Leverhulme Scholars for a second year from July 1st. Sir Holburt Waring was appointed, *ex officio* as President, a member of the Governing Body of the British Post-Graduate Medical School, to hold office from July, 1934, to July, 1935.

Mr. Claude Frankau has resigned his membership of the Court of Examiners as from the end of the July examination. His resignation was received with regret, and the vacancy thus occasioned will be filled at the Council meeting on August 2nd.

The following nominations were reported for the Primary Examination for the Fellowship beginning in Melbourne on November 29th: Assessor in Anatomy, Professor F. Wood Jones, D.Sc., F.R.C.S., F.R.S.; Assessor in Physiology, Professor W. A. Osborne, M.B., D.Sc.; Superintendent of Dissections, W. E. A. Hughes-Jones, F.R.C.S.

UNIVERSITY OF BIRMINGHAM

At the annual degree ceremony, on June 30th, the honorary degree of LL.D. will be conferred on C. A. Lovatt Evans, D.Sc., F.R.S., F.R.C.P., Jodrell Professor of Physiology, University College, London.

Medico-Legal

ALLEGED POISONING BY OYSTERS

In the King's Bench Division, before Mr. Justice Swift and a special jury, a case was heard on May 7th and following days in which Mr. Charles Frederick Wimple of Beckenham claimed damages from the Royal Victoria Hotel, St. Leonards, for supplying him with oysters which, he stated, brought about a severe attack of typhoid fever. The defendants denied negligence or breach of warranty, or that the plaintiff's illness was the result of his eating the oysters. They brought in as a third party the fishmonger, Mr. W. E. Baker, who had supplied the oysters to the hotel, and he in turn brought in as a fourth party the Seasalter and Ham Oyster Fishing Company, Ltd., from whom he obtained them. All denied liability.

Mr. J. E. Singleton, K.C., said that on a certain date in October, 1932, Mr. Wimple ordered two dozen oysters at the hotel, which were shared between him and two other persons (these others also became ill, although they did not suffer from typhoid). Some days after he returned home he became ill, Lord Horder was called into consultation, and a blood test confirmed the view that he had contracted typhoid fever. He was away from business for five months, and the special damages, subject to liability, were agreed at £525.

Dr. G. R. F. Stilwell of Beckenham, who attended the plaintiff, said that he had no reasonable doubt that the illness was traceable to the oysters. In cross-examination he said that he was aware that there was an outbreak of typhoid in Hastings at about that time. In reply to a suggestion that if the oysters were sent open from the fishmongers and remained on the hotel table for twenty minutes they might be contaminated by flies, Dr. Stilwell thought that unlikely at St. Leonards.

Lord Horder, in evidence, said that he was called in consultation to see Mr. Wimple in November, 1932, and came to the conclusion that he was suffering from typhoid fever. He judged that the onset of the disease had taken place about three weeks earlier, and that it was probably the oysters which had infected him. In general it was very uncommon for an oyster to become infected after it had been opened, and the care taken to prevent infection at the filter beds was shown in the fall in total incidence of typhoid. He agreed that if there were shown to have been five cases of typhoid in Hastings in 1932 it pointed to a source of infection in the town, and that if a number of those who suffered were not oyster eaters it indicated some other source of infection. One contaminated oyster was sufficient to have done the injury to the plaintiff, and the fact that

two other persons were taken ill after the meal made him suspect that the oysters were dirty.

In defence evidence was given as to the cleanliness and good management both of the hotel and of the fishmonger's premises.

Mr. Justice Swift, in summing up, said that if a hotel keeper supplied food which was contaminated and gave rise to typhoid fever—though he did not know of the contamination and might not have done anything careless—having undertaken to give food fit to eat, the law was that he must pay.

The jury found for the plaintiff, and assessed the damages at £725.

The second defendant, Mr. Baker, the fishmonger, did not contend that he had no responsibility to the hotel company, and accordingly, on a second action, a formal verdict was given for the hotel company against the third party for the amount awarded. A third action then followed as to the liability of the fourth party, the Seasalter and Ham Oyster Fishing Company, to indemnify the fishmonger.

New evidence was called to the effect that in October, 1932, there were in Hastings several cases of typhoid, though not amounting to an epidemic. One of the sufferers was a man who had eaten oysters bought at another fishmonger's shop, but which had been obtained from the defendant company. Professor R. T. Hewlett, bacteriologist, gave evidence that when oysters were infected with typhoid bacilli it was usually through the water in which they were laid, and that the danger of the oysters in question becoming infected after the fishmonger obtained them was practically negligible. To contaminate oysters in their bed the sewage content of the water would have to be pretty high, and if polluted water flowed over the bed he would expect a large number of oysters to become infected, and more than an isolated case of typhoid to occur. The reports of the Whitstable beds of the company in August showed absolute purity, as they did also in November, but in September they indicated the presence in the water and in the oysters of small quantities of various kinds of bacilli. Contaminated oysters which were transferred to clean surroundings might clear themselves in the course of a few days.

Dr. G. R. Bruce, medical officer of health for Hastings, gave evidence as to typhoid notifications in that town, and Major Austin Gardner, chairman of the Seasalter Company, said that the company had supplied many millions of oysters to all parts of the world, and during the past twenty years there had been no complaint as to their wholesomeness. Dr. J. F. Beale, bacteriologist to the Essex County Council, said that he had inspected the beds of the Seasalter Company for the past twenty-two years. The water of the beds was very clean, and bacteriologically was considerably better than milk.

After other evidence for the defence had been given Mr. Justice Swift said that no suggestion had been made against the way in which Mr. Baker handled the oysters or against the cleanliness of his premises. On the other hand, the Seasalter Company's oysters had had the highest testimonials. He put a question to the jury: "Has Mr. Baker satisfied you that the Seasalter Company supplied him with contaminated oysters?" and to this question the jury, after an absence of nearly an hour, replied, "He has not."

Judgement was accordingly entered for the Seasalter Company, and Mr. Baker was ordered to pay the costs of the fishing company and of the hotel company, a stay of execution being granted with a view to possible appeal. The judge said that he was afraid Mr. Baker must submit to being crushed between the upper and nether millstones.

The Services

HONORARY PHYSICIANS TO THE KING

Colonel D. P. Goll, I.M.S., has been appointed Honorary Physician to the King, vice Major-General Sir John W. D. Megaw, K.C.I.E., I.M.S., retired.

Lieut.-Colonel R. C. Priest, R.A.M.C., has been appointed Honorary Physician to the King and promoted Brevet Colonel, vice Major-General H. C. R. Hime, C.B., D.S.O., late R.A.M.C., retired.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

The House of Commons this week read the Unemployment Bill a third time. This Bill also secured a first reading in the House of Lords. The Commons took the second reading of the Finance Bill and of the Cotton Industry Bill, and had discussions on disarmament and on accidents in coal mines.

On May 9th Sir Henry Jackson presented a Local Government and Other Officers' Superannuation Bill "to amend the Local Government and Other Officers' Superannuation Act, 1922, and to make further provisions with reference to the superannuation of local government and other officers, and other matters connected therewith."

The Birmingham United Hospitals Bill was reported to the House of Commons, with amendments, on May 10th, and passed through report on May 15th.

On May 14th the South Devon and East Cornwall Hospital, Plymouth, Royal Albert Hospital, Devonport, and Central Hospital, Plymouth (Amalgamation, etc.) Bill was read a second time in the House of Commons.

On May 14th the Protection of Animals (Cruelty to Dogs) (Scotland) Bill was read a second time in the House of Commons.

The House of Lords, on May 15th, read the Water Supplies (Exceptional Shortage) Bill a third time, and passed the Protection of Animals Bill through its remaining stages. On the same day in the Lords the Registration of Births, Deaths, and Marriages (Scotland) Amendment Bill passed through committee.

The committee stage of the Betting and Lotteries Bill was set down for May 16th in the House of Lords.

A conference was arranged at the House of Commons, on May 16th, between hospital representatives, medical members of Parliament, and Peers to discuss the drafting of new clauses or amendments to the Road Traffic Bill to secure compensation to hospitals and medical men treating those injured on the roads.

The Parliamentary Medical Committee was summoned to meet on May 17th to consider the duty on arc carbons and the removal of the duty on insulin.

Minimum Needs of Unemployed

During re-examination of the Unemployment Bill on report, on May 9th, Mr. RHYS DAVIES moved to leave out Clause 39 ("Persons to whom, and circumstances in which, allowances may be granted"). He said the clause would make permanent what was called the means test as applied to a large section of the unemployed. Mr. KENNETH LINDSAY said Parliament should be more scientific in determining the minimum standard of allowances. For a man, wife, and three children the standard set up by the British Medical Association was 40s. 7d. Ordinary benefit fell below that figure unless extra shillings were given for the children. Mr. E. J. YOUNG said that whether the first 5s. of sick benefit from a friendly society was given in part compensation of inability to earn, or to provide extra nourishment during convalescence, it was unfair that it should be reckoned, under the Unemployment Bill, against a person who was recovering from an illness. Sir HENRY BLTERTON said the Bill was drafted to permit the Board complete flexibility in its regulations governing assistance. He had been asked about blind persons. So far as a blind person was put to special expense on account of his affliction it would be the duty of the Board to have regard to such expense in assessing his means.

Miss RATHBONE said she understood that, in answer to a deputation, the Minister had said that assistance should not be less than what was necessary to ensure to the applicant and his household, taking his resources into account, the minimum needs of healthy subsistence. That foreshadowed a revolution in the scale of assistance to unemployed people.

Under the scale of ordinary benefit a man getting full scale with no other resources would be far below those minimum needs. Taking the scale of nutrition adopted by the British Medical Association for a man, wife, and three children, the man, if he got the full ordinary benefit of 32s. a week, would have 2s. 3d. left over for rent and everything except food, clothing, and light. A man with five children had nothing left over for rent, and a deficiency on food and clothing needs of 5s. 3d.

The clause was retained in the Bill by 228 to 63.

On May 10th the report stage of the Bill was postponed. Miss RATHBONE moved an amendment to exempt from the Bill universities and their constituent colleges in respect of their employees, such as laboratory assistants, clerical workers, porters, and so forth, who were on the permanent staff and earned individually less than £250 a year. She said Oxford and Cambridge had successfully claimed exemption for the corresponding group of their employees. Other universities saw no reason why they should not enjoy this privilege. Sir HENRY BETTERTON opposed the amendment, which was rejected. The report stage ended on the same date.

Doctors' Cars and the Proposed Speed Limit

The Standing Committee of the House of Commons is considering the Road Traffic Bill. One provision in this measure is the imposition of a thirty-mile-an-hour speed limit in built-up areas. On May 15th the committee discussed a proposal to exempt from the limit fire engines, ambulances, and police cars. Mr. TOM SMITH proposed that doctors' cars should also be given this exemption to facilitate medical men attending cases of urgency. Mr. LLEWELLYN-JONES said that the result of this exemption might be that any doctor could exceed the speed limit at any time, and set up a defence, in case of a prosecution, that he was hurrying to an urgent case. If, in the event of accident in factories or mines, doctors and nurses were rushed to the scene in vehicles which exceeded the speed limit, he was sure that the courts would take a lenient view. Mr. OLIVER STANLEY said he could not recommend the committee to accept the amendment as it stood. It would be impossible for the police to detect when a car was going along a road whether it was a doctor's car, and if the doctor was going to an emergency case. That the driver was a doctor and was proceeding urgently might relieve him of prosecution, but he would be stopped by the police and his journey would be delayed; it was desirable there should be no delay in such circumstances. He would discuss the subject with Mr. Smith before the report stage, and see whether he could provide a suitable amendment. Mr. DAVID GREENFELD asked whether it would not be possible to overcome the difficulty by allowing doctors to carry distinguishing marks on their cars. No answer was given to this suggestion, and Mr. Smith, in view of the Minister's statement, withdrew his amendment.

Safety in Mines

On May 15th the House of Commons discussed the votes for the salaries and expenses of the Mines Department. Mr. E. BROWN said that there was no infallible cure for explosions in mines. The deaths over the last sixty years showed a large and progressive reduction. He did not agree with the statement that if there were enough ventilators there would be no explosions. In the Bentley explosion, in which forty-five lives were lost, the inquiry showed that the ventilation was as nearly perfect as possible. In the opinion of his advisers there were times and circumstances when it was impossible to prevent an accumulation of gas. He had made draft regulations with regard to automatic detectors, and on the following day the Mining Association and the Miners' Federation were attending at the Mines Department to present their views on the regulations. Replying later to the debate, Mr. BROWN said that classes for boys were held in a number of centres throughout the country, and were succeeding in making boys "safety-minded." The first-fruits of this work were shown in the decreased number of accidents. The Safety in Mines Research Board was applying itself with vigour to the problem of accidents, and was making its research available in popular form. Attention was being given to protective equipment to avoid the large number of acci-

dents to hands, eyes, feet, and heads, and experiments were being made with special types of gloves, "goggles," boots, and hats. He hoped to preside at a conference, which would be held at Swansea in June, to discuss the problem of dealing with silicosis. All the mining members representing South Wales constituencies would be invited to attend, and both mine-owners and miners would be heard. The Department had one inspector spending his whole time on this problem of silicosis, and a medical man was similarly engaged.

Insulin Prices

On May 14th Dr. BURGIN informed Mr. H. WILLIAMS that reductions in the price of British insulin were made in January. In the last few days the price of one brand of British insulin and of one brand of imported insulin had been reduced from 1s. 5d. to 1s. 4d. per 100 units. Sir F. FREMANTLE asked if it was not true that it was also sold to Poor Law authorities at 1s. per 100 units. Dr. BURGIN: That is the fact.

The second reading of the Finance Bill was the business of the House of Commons on May 16th. Clause 5 of this Bill runs: "Repeal of Customs duty on insulin. The Customs duty chargeable on insulin and its salts under Part I of the Safeguarding of Industries Act, 1921, shall cease to be charged, and the Import Duties Act, 1932, shall have effect as if insulin and its salts were included in the first schedule to that Act."

Verminous Premises in Sheffield.—Mr. SHAKESPEARE told Mr. Hamer Russell, on May 9th, that, under Part IV of the Public Health Act, 1925, which was in force in the city of Sheffield, the corporation had power to secure the cleansing of verminous premises, and when this was done it was not necessary to provide alternative accommodation. He would make inquiries concerning one case, in which it was suggested that cleansing was impossible owing to the nature of the property infected. Mr. FINE asked whether the medical officer in Sheffield had written that he possessed no power whatever to "proclaim" bug-infested properties.

Health Insurance on Leaving School.—Replying to Sir R. GOWER, on May 9th, Sir HILTON YOUNG said he had received resolutions passed by the insurance committee for the county of Kent which urged that, in order to secure to boys and girls entering employment a continuance of medical supervision, similar provisions in regard to age of entry should be made in respect of national health insurance as in the proposed new unemployment legislation, and that the school medical record in respect of such children should be made available for incorporation in the medical records provided in connexion with medical benefit. The subject, which involved administrative and financial considerations of great complexity, would receive his attention.

Maternity and Infant Welfare in Kensington.—In reply to Mr. James Duncan, on May 10th, Sir HILTON YOUNG said the Kensington Borough Council had provided a comprehensive maternity and child welfare service, which had recently been augmented by the appointment of a special whole-time medical officer. His information was that the service was constantly under review by the borough council; he was satisfied with the nature of these measures. Replying to Mr. West, Sir HILTON YOUNG said undoubtedly the effects of slum conditions upon infant mortality were direct. Mr. West asserted that 55 per cent. of the total deaths in West Kensington were of babies of the unemployed.

Diphtheria Inoculation in the Army.—On May 15th Mr. GROVES asked the Financial Secretary to the War Office the reasons which led to the decision of the Army medical authorities to discontinue the use of preventive inoculations against diphtheria. Mr. DUFF COOPER replied that no such decision had been taken.

Automatic Fire-damp Detector.—Mr. E. BROWN, on May 15th, told Mr. Conant that the Staveley Coal and Iron Company, after carrying out pit trials of the Ringrose automatic fire-damp detector at their Markham Colliery, had decided to equip with this detector each of the conveyor faces in two of the seams.

Voluntary Hospitals Commission's Report.—Sir ROBERT GOWER gave notice that on May 16th he would ask Sir Hilton Young whether he had given further consideration to the report of the Voluntary Hospitals Commission, and whether he proposed to provide public funds for hospital extension on the lines recommended.

Rural Water Supply Schemes.—Mr. SHAKESPEARE states that applications have been received for grants in aid of rural water supply schemes from thirty-seven rural district councils in respect of 175 parishes and from four urban district councils. The total cost of the schemes involved is £615,000. The applications are under consideration.

Notes in Brief

Sir HILTON YOUNG told Captain Erskine-Bolst on May 10th that he had no statistics showing the number of domestic servants who made use of the services of panel doctors in any given year, nor the percentage of those who did so.

Since the Borstal system was brought into operation nearly 11,600 young men have been licensed from Borstal institutions. Of 3,407 discharged on licence during the five years ended 1933, approximately 60 per cent. have not been reconvicted.

Proposals for the voluntary restriction of exports to the United Kingdom of condensed milk, milk powder, and cream have been accepted by Belgium, Switzerland, and Germany.

Medical News

Sir Gomer Berry and the Committee of Management of the Infants Hospital, London, have issued invitations to a dinner in the Guildhall on Wednesday, May 30th, to meet H.R.H. Prince George.

The annual dinner and dance of the West Kent Medico-Chirurgical Society will be held at Chiesmans Restaurant, High Street, Lewisham, S.E., on Thursday, May 24th, at 8 p.m. Reception at 7.30.

A meeting of the Medico-Legal Society will be held at 11, Chandos Street, W., on Thursday, May 24th, at 8.30 p.m., when Mr. W. J. Foster will read a paper on "Incapacity for Work within the Meaning of the National Health Insurance Acts," followed by a discussion.

A joint meeting of the Society of Medical Officers of Health and the Fever Hospital Medical Service Group will be held at 1, Upper Montague Street, W.C., on Friday, May 25th, at 5 p.m., when there will be a discussion on "Current Methods of Control of the Common Infectious Diseases," to be opened by Dr. H. Stanley Banks, Dr. E. H. R. Harries, and Dr. William Gunn.

A meeting of the School Medical Service Group will be held at the House of the Society of Medical Officers of Health, 1, Upper Montague Street, W.C., on Friday, June 1st, at 5.30 p.m., when Dr. Temple Gray will give an address on "The Bacteriology of Diphtheria." Members of the Fever Hospital Group and others interested are invited to attend.

We are informed that the annual general meeting of the British Institute of Radiology will be held at 32, Welbeck Street, W., on Thursday, May 31st, at 8 p.m., and not on May 17th, as announced in the *Supplement* to last week's issue (p. 252).

The thirty-fifth annual meeting of the Lebanon Hospital for Mental Diseases, Asfuriyeh, Beirut, Syria, will take place at the Westway Hotel, Endsleigh Street, W.C., on Tuesday, May 22nd, at 3.30 p.m., with Dr. Percy R. Smith, president, in the chair. The speakers include Dr. H. Watson Smith, medical director of the hospital, and Dr. Henry Wilson.

Founders' Day will be celebrated at Lord Mayor Treloar Cripples' Hospital and College on Monday, June 11th, when the Lord Mayor of London, the Lady Mayoress, and Sheriffs will visit Alton. After the meeting in the college hall at 1.15 p.m., presided over by Colonel the Hon. Frederick Lawson, chairman of the hospital, the wards, workshops, etc., will be open for inspection.

The Medical Prayer Union will hold its annual medical missionary breakfast at the Refectory, University College, Gower Street, W.C., on Wednesday, May 30th, at 8 a.m. The chair will be taken by Mr. W. McAdam Eccles, and Dr. Florence Robinson will give an address. The honorary secretary is Dr. Tom Jays, Livingstone College, E.10.

Meetings of the Tuberculosis Association will be held at Manson House, 26, Portland Place, W., on Friday, May 25th. At 5.15 p.m. a discussion on "The Palliative Treatment of Cases of Advanced Pulmonary Tuberculosis" will be opened by Dr. C. D. Agassiz and Dr. Ernest Ward. At 8.15 p.m. Dr. Jacques Stephani (Montana, Switzerland) will give an illustrated lecture entitled "Some Observations on the Value of Improved Radiological Technique in Pulmonary Tuberculosis."

The Fellowship of Medicine (1, Wimpole Street, W.) announces a further lecture-demonstration, on functional heart disease, at 11, Chandos Street, W., on May 29th (there will be no lecture on May 22nd). A week-end course at the Brompton Hospital will be given on May 26th and 27th, followed by a week's course in chest diseases at the City of London Hospital, Victoria Park (May 28th to June 2nd). A fortnight's course in gynaecology has been arranged at the Chelsea Hospital for Women from May 28th to June 9th, and a month's course in venereal disease at the London Lock Hospital from May 28th to June 23rd. There will be a week-end course in medicine and surgery at St. Mary's Hospital, Plaistow, on June 2nd and 3rd. A panel of teachers provides daily clinics in various branches of medicine and surgery. A debate will take place on May 30th, at 8.30 p.m., at 26, Portland Place, W., on the motion, "That in the absence of complications, surgical interference in cases of gastric and duodenal ulcer is unnecessary," with Lord Moynihan in the chair. The motion will be proposed by Dr. A. F. Hurst and seconded by Mr. Mortimer Woolf. Dr. Robert Hutchison, seconded by Mr. Herbert Paterson, will oppose the motion. All members and associates of the Fellowship, and their medical friends, are invited to be present.

A congress of the Italian Medical Association of Hydrology, Climatology, Thalassotherapy, and Physical Therapy will be held in June, partly at Acqui and partly at San Remo.

The nineteenth French Congress of Legal Medicine will be held at Lille from May 27th to the 30th, under the presidency of Professor J. Leclercq, when the following papers, among others, will be read: "Blood Groups in Legal Medicine and Anthropology," by MM. Lattes, D. Dujardin de la Rivière and Kossowitch; "The Painful Sequelae of Injuries and their Indemnification," by MM. Héger-Gilbert and de Laet; and "Contradictory Medical Expert Opinion," by MM. Raviart and Vullien. Visits will be paid to mines, sanitary institutions, and air parks. Further information can be obtained from the general secretary, Dr. Muller, 14, Rue de Friedland, Lille.

On May 10th the Duke of York paid his first visit to the new offices of the Industrial Welfare Society, of which he has been president since its inception in 1918. The society is an association of about a thousand firms who find it advantageous to pool their information on matters of health, co-operation, accident prevention, canteens, and working conditions. This store of information is available to any employer in return for a nominal annual subscription. The Duke welcomed those who were present, and said that members had been meeting at the old office for fourteen years, but that the society had long since outgrown the accommodation there. He believed that with returning prosperity the organization would soon outgrow even its spacious new home, for welfare work had now undoubtedly become an established branch of any progressive enterprise. As president, he welcomed to 14, Hobart Place old friends of the society, and extended an invitation to those many employers who had not yet availed themselves of the services it was so well equipped to render, and which industry had found so valuable in the past. His Royal Highness was received by Mr. Robert R. Hyde, the founder and director, who thanked the Duke for all that he had done for the movement.

The Committee of Award of the Commonwealth Fund Fellowships has made a number of appointments to fellowships tenable by British graduates in American universities for the two years beginning September, 1934. These fellowships are offered by the Commonwealth Fund of New York, of which Mr. Edward S. Harkness is president. The only award in medicine is to A. G. M. Weddell, M.B., B.S., of St. Bartholomew's Hospital Medical College, to the University of Rochester.

At the annual general meeting of members of the Society for Relief of Widows and Orphans of Medical Men, held on May 8th, with Mr. V. Warren Low, president, in the chair, the report of the directors for 1933 showed that £4,993 had been distributed during the year as grants to the fifty-three widows and six orphans, at present on the books of the society. Each widow over 75 received £90, those over 65, £85; and those under 65, £70; each orphan £60. Included in the amount distributed was £442 allotted to orphans to enable them to continue their school education or start on some professional career. It was stated that the by-laws of the society had been redrafted and brought into accord with existing practice, and that the Propaganda Subcommittee had been active in trying to obtain new members. By the payment of a small annual subscription a newly married man assures, in the event of his early death, that his widow and young children will not be left unprotected. At the present time the widow of a member, left with £125 per annum or under, is eligible for a grant. Membership is open to any registered medical man who, at the time of his election, is resident within a twenty-mile radius of Charing Cross. The secretary will give full information to any prospective candidate who writes to the offices of the society, 11, Chandos Street, Cavendish Square, W.1.

The Board of Education has approved an extension of the course—from eighteen months to two years—for blind students at the massage school of the National Institute for the Blind. Such extension is considered necessary in view of the wide range of subjects, which now include massage, remedial exercises, and medical electricity. All scholarships awarded by the Gardner Trust for the Blind for this particular study will be increased accordingly.

A State academy for racial and health welfare was opened at Dresden on April 14th, the first institution of the kind in the world, with Ministerialrat Dr. Ernst Wegner as director.

Professor Spillmann, dean of the Faculty of Medicine of Nancy, and Professor Mouriquand, who occupies the chair of paediatrics at Lyons, have been elected national corresponding members of the Académie de Médecine.

Dr. Alfred Shearer, who has been appointed High Sheriff of Montgomeryshire, is deputy coroner for Montgomery and surgeon to the county infirmary. For many years he has been chairman of the county Panel Committee. Dr. Shearer graduated M.B., B.Ch.Ed. in 1898, and had been medical officer of health for Newtown up to December, 1931.

Professor L. Lichtwitz, formerly director of the Rudolph Virchow Hospital of Berlin, has recently been appointed director of the medical department of the Hospital of New York.

Geb. Rat Anschutz, professor of surgery at Kiel, has been elected corresponding member of the Société Nationale de Chirurgie, and Professor A. von Eiselsberg, the well-known Vienna surgeon, has been elected an honorary member of the Surgical Society of Lyons.

A neurological investigation institute has been founded at Breslau under the direction of Professor Otfried Foerster, who has received a grant of 50,000 dollars from the Rockefeller Foundation.

On the initiative of Professor Lowenberg a centre for distribution of convalescent serum has been formed at Strassbourg, where, in the course of a year, three and a half litres of serum have been collected from thirty-five scarlet fever convalescents, 4,180 c.cm. from thirty-eight cases of infantile paralysis, and about a litre of serum from measles convalescents.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, *Aniology Westcott, London.*

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate Westcott, London.*

MEDICAL SECRETARY, *Madisera Westcott, London.*

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumshigh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

Unusual Symptom in Diabetes Mellitus

Dr. E. M. R. FRAZER (Burton-on-Trent) writes: The discussion on the white powder found on the boots of these cases prompts the memory to recall the story of the methods of a famous Edinburgh teacher who was renowned for his "spot" diagnoses of certain cases. For instance, he would astonish both clinic and patient by announcing, as soon as he saw the latter, what was his particular occupation by the soil on his boots, the colour of the hands, situation of trade callusities, and so on. If he saw an old gentleman with white powder on his boots he would announce that here was a case of diabetes mellitus and enlarged prostate, the sugar having dried out on the boots, and its site being determined by the small dribbling stream. This diagnosis would be clinched in hot weather by the presence of flies, feeding on the dried sugar.

* This Edinburgh teacher must have been Joseph Bell, surgeon to the Royal Infirmary, whom Sir Arthur Conan Doyle acknowledged as having served in part as the original of Sherlock Holmes.

Movement of Needles in the Tissues

"F. S. D. H." writes: The following may interest "Sceptic," whose query appeared on May 12th (p. 880): An ordinary sewing needle, carelessly left sticking in the back of an armchair, penetrated, and broke off, into the skin somewhere over my right scapula. An abscess formed, which was opened, but the needle was not removed. A small subcutaneous nodule remained, which slowly travelled in the course of the next year or two to my left axilla, where it disappeared.

Income Tax

Commencement of Partnership

"IN DIFFICULTIES" was engaged from February 1st to November 1st, 1933, as an indoor assistant, and received £r. Since November he has been carrying on his profession elsewhere, it having been arranged that he should enter a partnership as from January 1st, 1934—the agreement, however, has not yet been signed. On what basis should his return be made? He has not yet received any money for his work since November 1st, 1933.

* As regards the year 1933-4, our correspondent is liable to account for tax on (a) his earnings as an assistant up to January 1st, 1934, and (b) on his share of the partnership assessment for the three months to April 5th, 1934. For the year 1934-5 he will be liable as a member of the firm on his share of the firm's assessment, which will normally be based on the practice profits of the previous year—probably preferable to claiming to restart the calculations as if a new practice were set up as at January 1st, 1934. The fact that the partnership agree-

ment is not yet signed is immaterial. A visit to the office of the inspector of taxes to explain the exact position might save future trouble.

Endowment Policy for Child

"A. H. S." has just received the first of five annual payments under an endowment insurance policy for the education of his child. Is this liable as income?

** No. Assuming the policy to be drawn in the appropriate terms, the payments do not constitute an annuity, and merely represent receipts, which "A. H. S." has purchased by past payments to the insurance company.

Making a Return

"T. P." sold his practice on February 19th. All subsequent income will be derived from investments. What should his "return" consist of for 1934-5?

** The untaxed part of the income declaration should be marked *nil*, except as regards any investment income that may be untaxed, such as bank deposit interest, and the other part of the declaration should contain summarized particulars of his income. The professional earnings for the period April 5th, 1933, to February 19th, 1934, are not relevant, unless the practice has been regarded as ceasing and being restarted at the latter date; in that case the revenue authorities may call for particulars, not to make any assessment for the current year 1934-5, but to revise the assessment for 1933-4 if that course should be justified by the figures.

Loss on Sale of Car

"N. F." bought a car a year ago for the use of his assistant for £115. That assistant left and his successor brought his own car, so "N. F." sold the car for £29. Can he claim a deduction for the loss of £115 - £29 = £86?

** No. The income tax allowance extends only to the case where a car is purchased in replacement of the one discarded. The only allowance that "N. F." can claim is "depreciation" on the car while in his possession, say £115 at 20 per cent. = £23 + the (now) usual 10 per cent. — that is, £25 10s. in all. This is an example of the hardship which arises from the absence from the Income Tax Acts of any general allowance for loss of capital property, or even necessarily, employed in earning the income assessed.

LETTERS, NOTES, ETC.

Bee Venom for Rheumatism

Dr. HERBERT G. WHITE (Heathfield) writes: I was interested to read the letter of Drs. Shipton and Burt in the *Journal* of April 28th. About twenty years ago an agricultural labourer came to see me who was quite unable to work, being crippled with arthritis and unable to grasp the handles of a wheelbarrow. I recommended him to try bee stings. Accordingly, he went to a bee keeper and received half a dozen bee stings on each hand once a week. In three months' time he was able to return to work completely cured. Surely some of our manufacturing chemists should be able to put up bee venom for treatment of rheumatism; of course it would have to be less painful than the ordinary bee sting. I have frequently recommended others to try the cure, but have not been able to get them to submit to it.

Sterilization in Hereditary Disease

FRIEDRICH VON VERSCHUER, who is a director of the Kaiser Wilhelm Institute for Anthropology, Human Heredity, and Eugenics in Berlin-Dahlem, urges in the *Deutsche medizinische Wochenschrift* of January 19th the organization of a hereditary-biological census, which will tell the German nation exactly where it stands in the matter of the unit whose hereditary ailments qualify them for sterilization. In this connexion there should be special centres in which a card index could be kept of the subjects of hereditary disease. Hitherto the incidence of hereditary mental disease has been imperfectly known. In the case of the congenital mental defectives, for example, the statistical data at present available are most conflicting. According to a census taken in 1925 there were then about 100,000 mental defectives in Germany, of whom 46,000 were in institutions. But if attendances at schools for the backward be made the basis for a calculation of the total incidence of mental deficiency, then over a million belong to this category. As about 70 per cent. of the inmates of

asylums are schizophrenics, there should be about 190,000 such persons in Germany, but their number is higher than this according to some. After discussing in detail the national incidence of other diseases, such as epilepsy, deaf-mutism, and physical deformities with a presumably hereditary basis, and after calculating the approximate chances such persons have of passing these ailments on to their progeny, the author urges the courts concerned with this problem to hasten its solution by concentrating on the worst and most urgent cases, in which it is not difficult to express an expert opinion. There is, however, a growing number of more obscure cases about which investigations of whole families would have to be undertaken before an expert opinion could be given with regard to sterilization. Dr. von Verschuer pleads not only for research and the systematic collection of material on which to base it, but also for the education of the medical profession in this subject so that it may become hereditarily-minded.

The Word "Clinic"

Dr. L. FIRMAN-EDWARDS (Ryde, I.W.) writes: Is it too late to register a protest against the misuse of the word "clinic" to describe a place where patients (all walking cases) are seen, examined, or treated? The word as now used is becoming associated with this type of patient, whereas it obviously refers to a bedside examination. As first applied, it referred to certain establishments where patients were admitted as in-patients for special study, and in my opinion it should be confined to such institutions. But many so-called "clinics" have no facilities at all for clinical (that is, bedside) observation, and are merely out-patient departments or dispensaries for special cases. Would it not be better to reserve the term for the institutions to which it properly applies, and invent some new word for the purely out-patient department? "Centre" is a word which has rendered good service, and means what it says. Perhaps some other of your readers can suggest a better term.

Barbiturate Poisoning

Dr. STAFFORD GEDDES (Belfast) writes: In reply to Messrs. May and Baker's comments (April 28th, p. 786) on my letter (note on case of barbiturate poisoning, April 14th, p. 689) I wish to state that since reporting this case I have found that, by mistake, the patient was given a larger dose of sodium soneryl than he should have received according to his weight, which was eight stone. The dose given was five capsules (0.75 gram).

Disclaimers

Mr. ALECK BOURNE, F.R.C.S., writes: My attention has been drawn to a paragraph in the lay press of May 4th, which implies that I am a "super-specialist" (whatever that may mean) in a small corner of obstetrics. I have never claimed such a doubtful distinction; it is an absurd untruth, and the paragraph was inserted without my knowledge.

Mr. A. R. D. PATTISON, F.R.C.S., Newcastle General Hospital, Newcastle-upon-Tyne, writes: In its issue of May 10th the *North Mail* published a laudatory article in extravagant phrases referring to the work of the neurological surgeon at the Newcastle General Hospital. No name was mentioned, but it must have been obvious to anybody remotely acquainted with the facts that this article referred to me. The harmful effects of the article have been aggravated by the fact that certain charges for maintenance, which are made from time to time by the hospital authorities, have been quoted in a sensational manner as representing my customary fees. I should like to state emphatically that this article was published entirely without my knowledge or consent.

Messrs. EDWARD ARNOLD and Co. (Maddox Street, W.) write: It has been pointed out to us by Dr. William Brown that certain phrases in our advertisements of the third edition of his book *Psychology and Psychotherapy* might be construed as being contrary to the accepted principles of medical ethics. In view of this we wish to make it clear that the responsibility for these advertisements rests entirely with us, and not with the author, who did not know of their contents until they were published. Future advertisements will be suitably modified.

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 42, 43, 44, 45, 46, 47, and 50 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 48 and 49.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 260.

PRINCIPLES OF PSYCHOTHERAPY AS APPLIED TO GENERAL PRACTICE*

BY

C. STANFORD READ, M.D.

LECTURER IN PSYCHOLOGICAL MEDICINE, BETHLEM ROYAL HOSPITAL; CLINICAL PSYCHOLOGIST,
WEST END HOSPITAL FOR NERVOUS DISEASES

Though in the time we have at our disposal there is much ground to be covered on a specific subject, it will be worth while just to take a very cursory glance at the historical aspect of mental healing. The treatment of disease by mental means can be traced back to the earliest times. Its beginnings were of a magical nature and in the hands of the primitive medicine man, and later in those of the priests. Magic and theology became inextricably confused, and in the dark Middle Ages the "laying on of hands," exorcism, and miraculous intervention were the procedures employed to combat mental ills as well as much bodily disease. The superstitious credulity of those days is by no means non-existent now, and mankind is still actuated by the same motives and emotions as he always has been. Doubtless it was because of the mystical atmosphere in which mental healing had always been surrounded that until comparatively lately the whole subject was hardly thought worthy of serious consideration by the medical profession.

In the latter part of the eighteenth century Mesmer, a Viennese doctor, drew universal attention to his theory and practice of animal magnetism, or mesmerism as it came to be called. Though much of his work savoured of charlatanism it was through investigation of it that one form of psychotherapy became placed on a scientific basis. The theory of animal magnetism was negated, and the phenomena of hypnotism, as it was later termed, were found to be the product of suggestion. Although the practice of hypnotism never became popular, there were medical men of repute who specialized in it in all the capital cities of Europe. The work of Charcot in Paris and that of Bernheim and others in Nancy gave the subject a stamp of respectability. The studies of Janet in this realm and his psychopathological contributions mark him as a pioneer in our present-day psychotherapy. Hypnotic suggestion fell greatly into disuse, for it was found that curative results were so frequently as well obtained through simple suggestion alone. This method then held most sway, though a few employed what was known as rational psychotherapy or persuasion. About twenty years ago the psychological doctrines of Freud began seriously to influence our ideas of mental medicine, to such a degree that the analytic approach to mental disorder has now, to a vast extent, superseded all other forms of psychotherapy. It was the Great War that gave such an impetus to interest in psychological medicine and methods, and in latter years it has become increasingly evident that the general practitioner must make up for the deficiency in his medical curriculum and gain some insight into the principles underlying psychotherapy in order that he may extend his sphere of usefulness.

SCOPE FOR PSYCHOTHERAPY IN GENERAL PRACTICE

Hitherto, without such knowledge, his ability to understand and help a patient with neurotic disorder has been but small. He has had to fall back upon such trite remarks as "Don't worry," "You must control yourself more": just the things, in fact, which the patient would love to do but cannot. That is why he has come for medical advice. The inevitable nerve tonic and rest and change will then probably be advised. Should no progress

be made, the doctor tends to regard the patient's condition as one overstepping all reasonable pathology, and pays the patient out for this by accusing him of "Not trying to pull himself together," ascribing perversity to him, and withdrawing his interest entirely from the case. Such a state of affairs is rapidly passing away, and most practitioners recognize the fact that neurotic disorder cannot summarily be dismissed as unworthy of medical aid, and are, if no skilled help is available nearby, endeavouring to treat such patients themselves on modern rational lines. For many reasons the medical man in general practice is in a particularly advantageous position to apply, usefully and successfully, the principles of psychotherapy. True he has not the time, even if he had the knowledge, to use the more lengthy methods of treatment, but he will have ample opportunity to do a large amount of good. The family physician is in a special position of trust and confidence; he is regarded as one who understands the mental and bodily constitution of his younger charges, and especially those he brought into the world. He has a close link with his patients, and this gives him prestige and power. If only these factors are utilized in the right way his psychotherapeutic influence should be extensive. He sees nervous ills, too, at their earliest stages, when they are most amenable to treatment and more capable of being cured or alleviated.

THE IDEAL PSYCHOTHERAPIST

In speaking of the principles of psychotherapy we must first devote our attention to the psychotherapist himself. For many reasons one might say that a good psychotherapist is born, not made. With all the psychological knowledge in the world he will be of comparatively little use unless he has the right type of personality for this special work. He must be a man of the world, have wide interests and sympathies, be patient, able to identify himself with his patients, possess a love of humanity, and have not only an earnest desire to help, but the firm conviction that somehow or other he will be capable of doing so. This factor of personal conviction on the part of the doctor can hardly have its importance overstressed. Between doctor and patient, there is a subtle emotional interchange which, handled in the right way, can be productive of wonderful results. I often recall the fact that many years ago, when I believed so intensely in the curative effects of hypnotic suggestion and almost regarded it as the panacea for all ills, my capacity to hypnotize and alleviate or cure symptoms was astonishing. Now that my faith has been shaken in its wide application and my views lean towards a more analytic therapy, I find much diminished ability to produce hypnotic phenomena, and less success attends my efforts. All of us are cognizant of the fact that stupendous mental and bodily changes are brought about through earnest faith, whether it has its source in the spheres of personality, philosophy, or religion. Modern psychology has thrown much light upon its essential meaning, and it is the duty of the psychotherapist to understand the mental processes involved and direct them scientifically, instead of allowing the quack to flourish through the faults of omission and commission in medical practice. Faith acts through suggestion, a mental process we will deal with later.

* A lecture delivered to the Isle of Thanet Division of the British Medical Association on March 23rd, 1934.

FIRST STEPS IN PSYCHOTHERAPY

Presuming, then, that we have the psychotherapist who possesses the requisite mental attributes, what will his first step be when consulted? It should be to listen, listen attentively and understandingly, with but few, if any, interruptions. One is so tempted to make remarks or to stem somehow a flow of eloquence. Let the patient tell his story in his own words. This outlet, as a relief of mental tension by itself, is helpful. Worries, fears, apprehensive ideas, and guilty desires may, when kept to the self, create the feeling of being cut off, as it were, from the rest of the community. When a secret fear is shared with another this feeling of social ostracism is removed, and biological security and happiness tend to be re-established. This "catharsis"—or cleansing of the mind—this confession of troublous thoughts and emotions, must be the first stage in any psychotherapeutic treatment. From the initial experience of finding a sympathetic and understanding ear the patient will be encouraged to unburden himself still further, and to unload mental undercurrents that had, because of their painful content, been long-suppressed. When psychoanalysis as a form of treatment first saw the dawn it was known locally as the "talking cure," and though to-day this method has a highly developed scientific technique, popularly it might still thus be aptly described.

Having listened attentively to the patient's story the psychotherapist must orientate himself adequately to the case by questioning. Experience will enable him very quickly to get a brief longitudinal survey of the individual's life-history as regards his adaptations to early life, school, parents, family, husband or wife, social environment, and sex. With the knowledge now gained the doctor should be in a position to gauge the important factors of the severity of the neurosis, the type of personality he has to deal with, and what form of treatment will be best to apply. However, before any treatment is undertaken it is highly probable that certain attending circumstances will become a subject for discussion. In every neurosis there is the unconscious tendency to evade some duty or responsibility, to gain something, as it were, by the illness, and the question of whether or no the patient should not temporarily relinquish his work is frequently asked. Since it is true that all neurosis is in some way the result of a defective adaptation to life's stresses, so at the very outset we must stimulate our patient to face the continuance of his work, notwithstanding his feelings of growing incompetency and fatigue; encourage him to live a normal life; and resist the great temptation to take the path of least resistance. The neurotic has lost courage. He will for a time, at any rate, need a personal prop, but he must from the start be inspired with the need of standing on his own feet. Then there is the point of whether or no the patient is best treated while in his own home milieu or not. We may be sure that the neurosis is in some way intimately related to the emotional factors of home life. A father, a wife, some relation, or lodger, may be the situational pivot of the neurotic outbreak. One can lay down no hard-and-fast laws as to whether for the time being the difficult situation had not better be avoided until the patient is in a better position to adapt to it, or whether, the situation being what it is, it would not be more rational to face the inevitable straight away. In severe neurosis removal from home is practically a necessity; in mild cases such need may not arise.

Let us presume, then, that we have summed up the type of personality with which we have to deal, and have noted what form of neurosis the symptoms point to. The past history will probably also give us some indication of the amount of benefit we are likely to obtain. Having

got sufficient initial data, the question of what method of psychotherapy shall be employed has to be decided. There is too great a liability for hard-and-fast schools of psychotherapy to arise according to certain psychopathological theories held, in which only one form of mental treatment is used. We shall discuss these different avenues of therapeutic approach and recognize the principles upon which they are based. It will be seen that in varying circumstances our methods should differ accordingly. In the simplest imaginable neurotic trouble a heart-to-heart talk, a little added insight, a little advice, and some encouragement are all that is necessary. At the other end of the pole comes the severe and disabling disorder that requires a prolonged mental analysis to disentangle the disharmonies in the mind and to restore any measure of stability. As a generalization we may say that the long-standing cases with their much poorer prognosis had better be treated by simpler means, whereas the more recently developed neurosis should receive a deeper attention, since complete rehabilitation is the more likely. It must be borne in mind that the analytic approach in psychotherapy must involve intelligence in the patient and more expenditure of time and money. It is quite possible to be too scientific, and with our high aims forget the simpler means by which we may banish or alleviate nervous symptoms.

THE USE OF SUGGESTION

In our brief glance at the historical aspect of psychotherapy we noted that hypnotism was the method that held sway when mental healing was first seriously studied by the medical profession. It was shown by an English physician that hypnotic phenomena had no relation with animal magnetism, but were the product of suggestion. This psychological process of suggestion is a very potent force, and it is well that its power should be duly recognized and applied usefully in psychotherapy when called for. Consciously or unconsciously the physician is constantly employing it in connexion with his patients; and not infrequently this influence is neglected or misused. The expression of the doctor's face, the tone of his voice, the conviction of his assurances, and his expression of opinion on the patient's symptoms are all potent suggestive influences working for good or for ill. How often a nervous sufferer who on examination reveals no organic signs of disease is told there is nothing the matter with him. As if anyone consults the doctor without there being something the matter with him. There is no such thing as an imaginary disease, but there is a disease of the imagination. One must recall the true paradox that "if a man is ill enough to think he is ill when he is not ill he must be very ill indeed." The factor of being thus misunderstood not uncommonly has driven a patient to suicide, since he feels that if the doctor fails him all is lost.

Let us note some psychological facts about this suggestibility which should be helpful in its understanding, and therefore in its practical applications.

1. Some people are swayed by suggestion very much more than others. This is especially the case with children, who tend to accept any idea uncritically, since their reason and judgement are undeveloped, while in old age, where fixed ideas are the rule, any modification of the mind by this means is highly unlikely. Similarly, those who have their critical faculties well developed, and who therefore analyse any presented idea before acceptance, will not prove suggestible; while those who are impulsive, with less self-control, may easily become its victims. The suggestibility of an individual is enormously increased in the presence of others. This fact used to be taken advantage of when hypnotizing soldiers during the Great War. If all the subjects were in one ward, after the production of hypnotic effects in a few the rest

were almost in a state of hypnosis before any suggestions had reached them personally.

2. Then the same individual differs in his suggestibility according to various factors. Anything that lessens cerebral controlling forces will render him more suggestible. Fatigue, prolonged worry, a long illness, and hypnosis have such an effect. Alcohol, we know, inhibits higher control, so that when under its influence we are more amenable to suggestion.

3. We may be only suggestible to certain types of ideas—accepting those which flatter us and those we believe because we want to believe them.

4. We may be highly suggestible towards some people and not towards others. In the main we are in a submissive, receptive, and suggestible state in the presence of those who impress us with their power and superiority. From this we can well understand the suggestibility of the child to its parents and of the patient to his doctor. Friendliness, unity of aim, respect, confidence, and love all enhance suggestibility, and must be thought of in our psychotherapeutic aims. In hypnotism there is increased suggestibility, and it is because of this fact that one hopes to get definitely helpful results from specific suggestions which relate to the symptoms.

TREATMENT BY HYPNOSIS

It is not feasible here to deal with the method of the induction of hypnosis, but every medical practitioner should acquaint himself with sufficient knowledge of the subject so that he may employ it on occasion. I am inclined to think that the use of hypnosis has been somewhat too much neglected since analytic therapy has come to the fore. In many minor ways its employment may be helpful, while in such conditions as fugues, amnesia, and dual personality it is of inestimable value. In hypnosis there is a widening of the memory field, and verbal suggestions produce, not only mental effects, but effects on bodily processes which normally are controlled by the voluntary or involuntary nervous system. Thus suggestions can modify salivary or mammary secretion, the peristalsis of the bowel, vasomotor processes, and the functions of menstruation. There is a very close rapport between the doctor and patient; this is of interest, and will be referred to later.

During the hypnotic state the curative suggestions can be made in different ways, varying somewhat according to the patient, the kind of symptom, and the doctor's custom. They may be made in a commanding or gentle tone, the former constituting a masculine approach and the latter a feminine. They may be directed immediately against the symptom, or an indirect attack may be adopted. Given an average suggestibility, there is the tendency for indirect suggestion to be far more effective, as the critical attitude is thereby disarmed and no contra-suggestions tend to be formed. Naturally repetition of these suggestions adds to their therapeutic force. It is to be noted, however, that apart from any specific verbal suggestion the mere induction of hypnosis itself may not uncommonly do good, and minor symptoms occasionally thus disappear in a striking manner. Unfortunately there is a somewhat deeply rooted prejudice against hypnotism on the part of the public, due to the fallacious idea that it is dangerous and not right that a person should be dominated by the will of another. Nevertheless, in practice I have seldom found any such objection sustained after a reassuring explanation. Some time after hypnotic phenomena had been scientifically studied it was found that just as good medical results could be obtained through suggestion in the waking state with the patient in a condition of absolute passivity of body and mind. Those who have had ample experience in the use of hypnotic and simple suggestion do not find, in the main, noticeable advantages in the former method, notwithstanding the heightened suggestibility of the hypnotic

state. Suggestion, therefore, to-day is mainly employed in this way. In both cases similar conditions for success are necessary on the part of the subject—fixation of the attention, monotony of impression, limitation of voluntary movements, limitation of the field of consciousness, and inhibition of all distracting thoughts. Suggestion while the patient is asleep, too, is possible, though seldom called for. In the case of children, difficult otherwise to treat, such a method is to be borne in mind.

SOME POINTS IN SUGGESTIVE THERAPY

Though there is insufficient time to discuss the psychology of suggestion, it will be interesting to note the psycho-analytical theory concerning it. According to this, suggestibility is the unconscious desire to believe blindly and to obey without criticism which originated in the child-parent relationship. It is the expression of a latent tendency to be persuaded by love (or intimidated by fear), and is due to the establishment of a relationship between the person who receives the suggestion and the person who gives it, which is an unconscious reactivation and transference of the relation that existed in infancy between the child and a loving mother, or a stern or imposing father. An affective bond, we know, does form in hypnosis between the subject and operator, and this rapport that exists is undoubtedly a necessary factor for success. At the same time, this link between doctor and patient must not be allowed to become an exaggerated one. For suggestive treatment the object is to produce a condition of mind which will set in action the right affective forces for the induction of those states of suggestibility which will harmonize with and reinforce the ideas to be suggested, and so to get them accepted with conviction. First the state of personal suggestibility should be induced by arousing the necessary instinctive tendencies, showing the patient sympathy, and impressing him with a knowledge of, and interest in, his condition, so that he has respect for, and confidence in, the physician. The personality of the physician and his attitude is thus perhaps his greatest asset in this form of psychotherapy. The individual should wish to be cured, and the whole atmosphere should be one of cure. A quick insight and an investigation of the case will show how the suggestions should be arranged and what form they should take. Repetition is naturally an important factor. The response to suggestion made may be positive, negative, or neutral, according to whether it is accepted, opposed, or simply not accepted.

AUTO-SUGGESTION

You will note that I have not referred in any way to auto-suggestion. I have not done so because I doubt its validity. In endeavouring to get away from the old idea that the will-power of the operator in hypnosis was the main factor, and the subject merely a tool in his hands, the disciples of M. Coué went to the other extreme, and negated the psychological forces involved in the operator altogether. That auto-suggestion has at times been employed with success I am willing to concede, but in such instances the personal influence is executed through the reading of a book or through the repeating of phrases previously spoken by a physician. The use of the word seems so wide and loose that it loses all value. The principle that the wish is father to the thought is so generally at work in our minds that almost all our mental processes, except the highest intellectual ones, would fall under the heading of auto-suggestion. We should be on much safer ground if we view suggestion as a phenomenon resulting from the interplay of emotional forces between two individuals.

LIMITATIONS OF SUGGESTIVE THERAPY

If we criticize suggestive therapy it can be judged by the results obtained by its use, and also by how it agrees with the principles of treatment based on our knowledge of disease. The results vary very much. At times they seem miraculous, and the beneficial effects may be permanent. Cured cases, however, are often only seemingly cured and relapse later, and further courses of treatment are necessitated. Where we are dealing with neurotic disorders—and in the vast majority of instances suggestion is only employed in this sphere—there is no attempt to investigate the inner life of the patient nor any endeavour to get at the basal causes which, we now have good reason to believe, depend upon mental conflicts. This is unscientific, and it is impossible to foretell whether any real lasting benefit is likely to accrue, because the morbid source is never attacked. Unfortunately Baudouin's statement that if we only suggest the cure the subconscious mind will always find the way is not borne out by experience. The great disadvantage of suggestion, therefore, is its blind nature. The belief in the magical effect of mere words is an irrational one, and reflects a primitive type of mind. Nevertheless, there is a distinct field for the employment of suggestion if only it be applied to the right human material. In the realm of the psychoneuroses it should be used when, for any reason, a more scientific and analytic approach is not feasible. In intractable and severe long-standing neurotic disorder it may prove beneficial in alleviating symptoms, but, if possible, the earlier cases should be dealt with more radically. Advance in age, and lack of intelligence are factors which commonly stand in the way of an analytic method. In the case of organic disease—and not infrequently a neurotic element becomes superimposed—the drawbacks to suggestion which were mentioned do not apply, and in the future such a therapy may prove useful in this realm.

ON PERSUASION

In considering other psychotherapeutic measures we shall note that we are getting away from the blind nature of attacking symptoms and are endeavouring to obtain the conscious and active co-operation of the patient in our efforts towards his betterment. Nevertheless, in the intimate relationship existing between doctor and patient the unconscious factor of suggestion can never be entirely eliminated. The doctor has always been wont to appeal to the individual's reasoning power, and to try to combat neurotic fears by his assurances that they are groundless and that only added insight and more self-control are needed to overcome them. The hysterical paraplegic is told at some length that walking is quite possible if only the idea of incapacity in that direction is banished. This method of so-called "persuasion" has been, and is still, employed, so that its principles should be examined. Here the therapist presumes that, if he explains the meaning and the origin of the symptoms, the patient has the capacity to modify the morbid mental processes. Much, however, depends upon whether the physician does really know and understand the meaning and origin of the symptoms. Commonly enough these symptoms are only taken at their surface value, so that any explanation can have little or no effect and the process is just as much floundering about in the dark as suggestion is. If we take up the attitude, as we must in the light of modern knowledge, that neurotic illness is motivated by factors below the threshold of consciousness, it is evident that any superficial attack by itself is futile. A very small experience should make us realize that logical reasoning has little power to modify what goes on in the

mind. The obsessional neurotic is frequently highly intellectual, and is only too convinced of the absurdity of his compulsions, fears, and doubts; yet he is impotent to inhibit them. The physician who has little or no insight into these forms of pathological disturbances is only too apt to regard them as largely due to mere irrational habits of thought and a lack of will-power. Were such premisses largely true, one would expect persuasion to bring about beneficial results, but unfortunately experience teaches us otherwise. Will-power is not a special faculty that can be stimulated. The will is the whole character in action. It is not that symptoms arise from a weakness of will, but that some underlying emotional impulse is too strong for normal control. Nevertheless, I am by no means trying to convey the idea that this method has no value whatever, for, as we shall see later, when it is combined with a preliminary investigation and understanding of the deeper sources of the neurotic symptoms, in the simpler type of cases much good can be accomplished. Without some knowledge of the pathological reactions taking place any good that may eventuate will be due to the unconscious suggestive influence of the physician.

Another psychotherapeutic method not uncommonly adopted has been that of attempting to divert the patient from his symptoms and resulting self-centredness without any real understanding of them. The going away for a change of scene has been the most usual recommendation given to a nervous sufferer, with the hope that constant distraction will gradually give the symptoms the chance of withering away from inattention. This by itself is a poor way of attacking the problem, for a person cannot thus run away from his own ego. Nevertheless, when the diversion from symptoms is carried out more scientifically by the development and encouragement of useful and personal interests which will tend to drain off energy from pathological channels into healthy ones, much benefit may follow. Unfortunately, however, experience shows that those who can be helped in this way are comparatively few in number, since the morbid forces seem too strongly fixed to be thus diverted. Combined with other methods of psychotherapy though, this diversion of forces is a sound principle, and should always be thought of. Because of its diverting value and the dangers attendant upon evading responsibilities, the giving up of work should not usually be advised.

VALUE OF RE-EDUCATION

We now come to another psychotherapeutic approach, which is still more rational and in which the patient takes a much fuller share. It has been termed "re-education." The physician, believing that the neurosis depends upon mental factors of which the patient is mainly unaware, carefully takes a longitudinal survey of the life-history, discovers the emotional disharmonies to which the individual has been subjected and the reactions to them, and notes the psychological traumata of the past. By such means he sums up the type of personality he is dealing with, and discovers, if possible, the pathological processes that are responsible for the symptoms. With this knowledge he proceeds to explain to the patient the significance of his past in relation to the present disorder, and endeavours to modify the attitude that has been taken up, to render that attitude more rational, to encourage the general interest, to give a new goal to life, and generally to broaden the mental horizon. Here there is a distinct advance, in that hidden causative and unconscious mental factors are investigated and taken into consideration, instead of only dealing with the end-product of symptoms. The patient cannot help but feel gratified

that his case is worthy of such investigation and that he is understood, while the point that he finds that he himself has to be the main agent in bringing about a cure is extremely important. Provided the physician is well equipped with modern psycho-pathological knowledge, so that his mental examination is on the right lines, we shall find that the re-educative method will be most applicable to the majority of cases met with in general practice, and will be productive of most good. From a strictly scientific point of view it may well be that the investigation of the mental factors cannot be sufficiently prolonged or probed deeply enough, and that much pathogenic material lying in the unconscious mind remains untouched. Be that as it may, it is quite evident that in practice, for many reasons, it is impossible to do more.

THE ANALYTIC METHOD

Lastly, we come to the analytic method of psychotherapy. Using the word analysis in its ordinary connotation such a method involves the scientific sifting out of the varied past and present mental processes and reactions of an individual in order that the pathogenic source of the neurotic symptoms may be traced, their meaning understood, and a rational therapy made possible for their alleviation or cure. Psychology teaches us that only a comparatively small part of our mental functioning lies in the region of our awareness, and that for the real motivation of most of our thoughts, feelings, and actions the deeper unconscious mind must be explored. It is now fairly established that mental conflict in some way is the root cause of most neurotic disorder, and that this disharmony is due to the presence in the unconscious mind of emotionally toned groups of ideas and impulses which, being alien to the main body of the personality, have been refused recognition and become dissociated from it. Such complexes lying repressed in the unconscious are essentially dynamic in nature, the underlying urges striving for outward expression but being directly prevented from doing so by the inhibiting influence of the ego. The neurotic symptom appears in a disguised form as a compromise between the two forces, so that it is not recognized for what it really is. Such disguises are manifold; many require much patience and analysis to unveil; while others may be more or less rapidly recognized through our knowledge of psychological mechanisms.

For instance, the mental mechanism of projection, which involves the conception that an inner mental process seems to be existent in the external world, is one of the commonest ways in which we disguise painful thoughts from ourselves. The very fault we see so much in others is really ours; the husband who manifests exaggerated jealousy of his wife does so because the idea of his own leanings towards infidelity is too much out of harmony with his self-respect for him to recognize and accept. This mechanism of projection is what hides the real meaning of many a morbid fear. It seems to be a fear of some external danger; but in reality it is an impulse, a desire within ourselves of which we are afraid. The old spinster who cannot get into bed without looking under it for fear there is a man there develops such a symptom as a defence against her biological craving for the male. The patient with agoraphobia, or the fear of being alone in the streets, may be really in terror of being exposed to temptations which his ego yearns for but which his conscience forbids and represses from his conscious mind. The insane patient who constantly hears voices from without accusing him of vicious practices and calling him by opprobrious names is projecting that blame which he dare not give himself.

THE OBJECT OF ANALYSIS

Now the object of analytic psychotherapy is to bring these buried complexes into consciousness so that they may be duly recognized by the patient and assimilated by him as part of his personality. It is essential to see that consciousness can deal with and control a mental process that is itself conscious far better than one that is not. In our everyday life we know how various little tricks of conduct we had got into the habit of manifesting, but of which we were unaware, can be successfully dealt with when our attention is drawn to them. In this way, too, mental energy which has been unhealthily bound up with the repressed complexes and the formation of neurotic symptoms can be released and diverted into useful and social channels. The mind thus, instead of being divided against itself, tends to become a harmonious whole. It must be understood that mere intellectual appreciation of a complex on the part of a patient will be of little or no avail except in so far as he grasps the fact that the source of the trouble is resident within his own mind. Otherwise, an experienced psychotherapist might at a first interview accurately spot the pathogenic forces at work. But merely imparting such knowledge will not help. There are strong internal resistances within the patient's mind which must be overcome before he can accept the truth about himself and assimilate it emotionally. Neurotic symptoms constitute a defence against the recognition of something within the self; that is why from one point of view we can speak of "a will to illness," and why a psychoneurosis is difficult to modify and cure.

Since we are only dealing briefly with the principles of psychotherapy, this is no occasion to discuss any further the intricate psychological points involved in the analytic method. As you probably know there is more than one school of psychopathology, and the trend of any analytic investigation will depend upon what particular theories are held. It would carry us much too far afield to speak of them. Anyone sufficiently interested must consult suitable literature on the subject. All would agree, however, in regarding a so-called nervous disorder as due to mental factors of which the patient is quite unaware, and that some form of analytic therapy is the ideal method of treatment. It has already been pointed out that hypnosis, simple suggestion, persuasion, and re-education all have their useful applications. The psychotherapist must not pin his faith to any one method, but must be prepared to employ them all as occasion demands. Suggestive influences cannot be eliminated from any one method because of the special relationship that exists between doctor and patient, though in analysis it is reduced to a minimal degree. The practical side must ever be kept in view—in general practice especially. The severity of the neurosis, the amount of the maladaptation to social life, the suffering involved, the disturbance of the capacity to work, the age of the patient and his intelligence, the situational factor, time, and expense—all have to be taken into consideration. It may be that the disturbance is slight, so that a short psychotherapeutic conversation or two, assurances given that the individual is not "going off his head," and stimulation to face the difficulties of life with greater courage will be all that is necessary. It may be that the age of the patient is too advanced for any active interference. It may be that the symptoms patently depend upon some comparatively simple domestic problem which necessitates interviews with other members of the family to bring harmony into the home. In some cases it will be seen at once that pathological investigation must go deeper for later treatment, as seems fit; while in others it is evident that

more expert knowledge and treatment is called for. In a certain proportion of cases the technique of Freudian psycho-analysis will hold out the best chances of cure. Those patients who, for any reason, cannot be adequately treated by the general practitioner can be referred to one or other of the many clinics which exist for this purpose. It will, however, add greatly to the interest of general practice work if the doctors themselves further their psychological knowledge and learn to apply it themselves.

CONCLUDING REMARKS

It is not feasible here to speak of the types of cases to which psychotherapy should apply. In some degree it may be said that every patient will need some of its applications, even if it be only that of instilling cheerfulness, hope, and courage. It is in this way that the personality of the physician, his bedside manner, and the atmosphere he creates in his consulting room mean so much. Conan Doyle told us a short story of two youthful medicos, lately qualified and well versed in the use of all the latest medical knowledge and appliances, who set up in a small community as partners. The other doctor there was an old man with a lovable personality, who had been there for many years, and who was by no means up to date in his work. After their courtesy visit the budding practitioners laughed among themselves at his age and ignorance, pitied his patients, and came to the conclusion that before long he would not have many left when their academic superiority became recognized by the inhabitants. Soon afterwards, on the outbreak of an epidemic of influenza, one of the young doctors was struck down. As he lay in bed feeling very sorry for himself the thought of the scientific attitude of his partner at his bedside had no attraction for him, whereas the presence of the old doctor, he felt, would bring peace and comfort. He therefore sent for the latter, but found that his partner, who had been taken ill as well, had also sent for the old man they had both so much derided. The moral is obvious.

Though it is in the realm of the psychoneuroses that psychotherapy especially applies, it must be borne in mind that psychogenic factors so frequently have bodily manifestations. The old hugaboo of the relations existing between mind and body must be relegated to the dust-beap. We must regard body and mind as simply different aspects of an individual who is a psychosomatic unity. All the emotions have their physical expressions. It is therefore important in every patient to view the individual as a whole and take into careful consideration possible psychological factors as well as bodily ones. In time experience will teach you that the mental element enters far more into disease than you ever dreamt of. The increased heart-beat may be due to a secret fear; the lump in the throat the result of an insult that cannot be swallowed; the obstinate feeling of nausea or vomiting may be the sequel of the inability to digest a psychic situation with a resulting buried complex of disgust and revulsion. We do not for nothing speak of a sickening horror or of having a nasty taste in our mouth after reading something of a disagreeable nature. All our emotional feelings may be expressed somatically, and if long continued may bring about definite organic disease. Superficial inquiries, at any rate, should always be made into the emotional life, into the possibility of there being ungratified instinctual yearnings; and the sphere of sexuality must not be neglected. Your patient must be viewed not as a "case," but as a human personality that somehow or other is maladapting to his environment. In dealing with the human body never forget the human heart. With the earnest desire to understand, and with a comparatively small knowledge of medical psychology,

the practitioner will be surprised at the fresh light that will be thrown on many recalcitrant symptoms.

Now a word as to prognosis. Commonly enough too much is expected of the psychotherapist. Just as we come across people with poorly developed chests who will always be liable to coughs and who break down under respiratory strain, so we meet with a constitutionally poor mental soil that will ever be apt to find it difficult to withstand the stresses of life without developing symptoms of maladaptation. Whatever method we adopt in psychotherapy we must be prepared to face the fact that we cannot make some individuals normal, but perhaps can alleviate to some extent and render life more bearable. The less we use the word "cure" in psychotherapeutic practice the better. On the other hand, at times brilliant success may be achieved. Those of you who are sufficiently interested to learn more of that hitherto neglected subject—psychological medicine—will find it a most engrossing study, and one that will greatly enhance your usefulness as a physician.

INADEQUATE IMMOBILIZATION AND NON-UNION OF FRACTURES*

BY

R. WATSON JONES, M.Ch.Orth., F.R.C.S.

LECTURER IN ORTHOPAEDIC PATHOLOGY, LIVERPOOL UNIVERSITY;
ASSISTANT SURGEON AND IN CHARGE OF ORTHOPAEDICS,
LIVERPOOL ROYAL INFIRMARY

The crippling disabilities which at one time resulted from excessive immobilization of joints in the treatment of fractures entirely justify the recent wave of enthusiasm for early mobilization and functional activity. The essential principle of modern treatment is complete immobilization of the fracture, with at the same time active movement of every joint which need not be immobilized. When this principle is observed massage treatment becomes unnecessary, incapacity periods are reduced, and many permanent disabilities are avoided. But there is some danger of undue enthusiasm and of misrepresentation of the principle, so that the mobilization of joints is allowed to interfere with the immobilization of the fracture. It must be recognized that complete immobility of the fracture is a primary necessity, that there must be no mobilization except in joints which need not be immobilized, and that mobilization should be the result of the patient's own active exercise and not of the passive manipulations of the masseuse.

A fracture of both forearm bones was recently plated by a distinguished surgeon, and from the time of operation the arm was taken daily from its splints for two hours of massage and passive movement. The constant strain on the fractures had not only caused non-union, but had produced painful spasm of the muscles and stiffness of the joints, which was even greater than if there had been no movement at all. When the fractures were completely immobilized by a plaster cast active finger movements could be practised without pain and improvement in the range was immediately observed.

Such gross misapplication of the principles of early functional activity in fracture treatment is rare. Unfortunately, however, equally disastrous results are not uncommonly seen when the principles have been misapplied in a less obvious manner. In one group of cases splints or plaster have been inexpertly applied so that the fracture has not actually been immobilized at all. Angulatory movement may have been completely con-

* A paper read in Manchester on March 8th, 1934, at a joint meeting of the Liverpool Medical Institution and the Manchester Medical Society.

trolled, but the fact that rotatory torsion strains inhibit union just as certainly has been overlooked. In the second group of cases complete immobility has been maintained for six or eight weeks, but the joints have then been mobilized before the fracture is sufficiently consolidated. These two factors—incomplete immobilization and immobilization for too short a period—are the factors responsible for delayed union and non-union, whether in the shaft of a long bone such as the tibia, the humerus, or the ulna, in the neck of the femur, or in the carpal scaphoid bone.

The many theories of inadequate blood supply, impaired nutrition, inaccurate apposition of fragments, failure of impaction, the inhibitory action of synovial fluid, and the absence of blood clot are of no real significance. The only important cause of non-union is inadequate immobilization.

HYPERAEMIC BONE DECALCIFICATION AND NON-UNION

Recently acquired knowledge of the calcium content of bone in relation to its vascularity provides the pathological basis for these clinical observations.¹ No longer are we confused by the suggestion that although the decalcification of infected bone is obviously the result of an increased blood supply, the decalcification of fractured bone, such as the fractured neck of the femur, is due to impairment of its blood supply. Hyperaemia of bone always results in decalcification, whether the blood supply is increased by injury, by infection, or by the growth of a neoplasm. Increased calcification or sclerosis, on the other hand, is the result of impairment of blood supply, as may be seen in syphilitic periostitis and Charcot's disease, where there is endarteritis obliterans, or in the late stages of osteomyelitis, where the early infective hyperaemia has been replaced by the ischaemia of reparative fibrosis.

The same hyperaemic decalcification and ischaemic recalcification may be observed in fractures. The initial traumatic hyperaemia gives rise to decalcification of the bone ends. So long as the hyperaemia persists, decalcification goes on: not until it has subsided can calcium salts be redeposited in the young connective tissue which has grown between the bone ends to form callus. When, with the final stages of repair and fibrosis, the blood supply is impaired, the callus undergoes dense calcification with consolidation of the union.

If, on the other hand, the fragments are imperfectly immobilized, the shearing and twisting strains tear the young connective tissue between the fragments. The repeated traumatization gives rise to constantly recurring hyperaemia, and more and more of the bone ends undergo decalcification. A crack becomes a cavity, a linear fracture becomes a gap fracture. When, finally, there is repair and fibrosis there is no continuous bridge of callus to recalcify, sclerosis is observed in the plaque of bone across the concave bone ends, and non-union is established. Even when the fracture has been properly immobilized for several weeks so that the initial hyperaemia has subsided and recalcification has begun, if it is then repeatedly strained before the stage of final dense consolidation the same traumatic hyperaemia is observed. Recalcification ceases at once, decalcification supervenes, and non-union develops.

FRACTURES OF THE CARPAL SCAPHOID

Fractures of the scaphoid illustrate very clearly the three stages in the life-history of an ununited fracture. Within a few days of injury the crack is so fine that it may be overlooked in radiographs, and, indeed, it may only be possible to suspect it even with the aid of a magnifying lens. But if it is not immobilized the

traumatic hyperaemia of movement of the fragments on each other gives rise to decalcification and the appearance of a cyst. This intermediate stage of non-union persists from about one to four or five months after injury, and the fracture will still unite if it is immobilized. In the third stage, reparative fibrosis and ischaemia have caused recalcification; the "cavity" has partly filled in, but the surfaces of the fragments are dense and sclerosed. Obviously it is now wasted effort to immobilize the fracture without first breaking up the sclerosis, refreshing the fractured surfaces by multiple drilling, and so allowing revascularization of the bone surfaces and of the intervening fibrous tissue.

The last 100 cases of fracture of the carpal scaphoid which were immobilized at the Liverpool Royal Infirmary may be analysed as follows:

One Hundred Fractures of Carpal Scaphoid Bone

	Number of Cases	Average Period of Immobilization	Number of Cases of Non-union	Percentage Securing Bony Union
* Recent fractures of waist and tubercle	65	2 months	None	100
* Recent fractures of proximal pole	6	5½ months	1	83
† Old fractures of waist and proximal pole	25	7½ months	1	96
† Old fractures of waist with dislocation semilunar	5	16 months	2	60

* Recent—less than 1 month old.

† Old—less than 1 year old (drilling in 13 cases).

Cases older than 1 year (usually with osteoarthritis of the wrist) were not immobilized.

It is evident that in recent fractures, even including the difficult polar fractures, bony union may be secured in 98 per cent. of cases by complete immobilization with an unpadded plaster cast. The average duration of immobilization is little over two months, but occasionally it is necessary, even in recent fractures, to continue for six or twelve months. *If in every case immobilization had ceased after two months there would have been a high frequency of non-union; but by continuing immobilization until the radiograph shows evidence of consolidation every one unites by bone.* Similarly, when treatment is delayed for several months, it is still possible to secure union in the majority of cases, but drilling is frequently required and it may be necessary to maintain immobilization for as long as twenty-two months.

These statistics compare most favourably with the results which were at one time secured by the inadequate immobilization of a cock-up splint for a few weeks. With such treatment bony union was the exception rather than the rule.

FRACTURES OF THE NECK OF THE FEMUR

In subcapital fractures of the neck of the femur we have another example of a fracture in which apparently trivial movement, especially rotatory movement, is sufficient to perpetuate traumatic hyperaemic decalcification and to delay or to prevent union of the fragments. It is generally believed that a high fracture of the femoral neck is completely immobilized by a plaster spica extending from the toes to the upper chest. Special precaution may have been taken to flex the knee so that the limb cannot rotate within the plaster; but the fact that the upper fragment can rotate is overlooked. Every surgeon who operates on such a case is impressed with the extraordinary mobility of the detached head of the femur. It has no attachments whatever, apart from the ligamentum teres, and it can twist and slide within the acetabulum even when the limb below it is held rigidly immobile. Moreover, in the obese patient it is practically impossible

to mould the trunk part of the plaster in such a way that the pelvis is prevented from rotating.

It is this constantly repeated rotation movement of the fragments which accounts for the decalcification and absorption of the neck of the femur with non-union which is seen in about 50 per cent. of the cases so treated. Even in the 50 per cent. which do ultimately unite the same decalcification is seen in the shortening of the neck of the femur which almost always occurs, and which proves that the hyperaemia due to the trauma of movement has continued long after the hyperaemia of the initial injury subsided. There is no such thing as a "dry fracture" of the neck of the femur; the capsule of the joint is always distended with blood. The distal fragment is more vascular than the proximal fragment, and it is the distal fragment (the neck of the femur) which undergoes the greatest decalcification and absorption.

The stainless steel Smith-Petersen nail is made in such a way that the length of the nail prevents angulatory movement, and the three flanges prevent rotatory movement. With the nail driven centrally through the head and neck of the femur immobility is absolute. For the first time in the history of the treatment of fracture of the neck of the femur we have prevented rotational strain and movement, and for the first time we have a method which secures union of the fracture in 90 to 100 per cent. of cases. Moreover, shortening of the neck of the femur from the decalcification of continued movement of the fragments is no longer observed.

I have operated on twenty-eight subcapital fractures of the neck of the femur with one death. Of the twenty cases in which a stainless steel nail was inserted more than twelve months ago, all have united by bone except one, and this single failure was a case in which the nail was removed four months after operation, before there was radiographic evidence of consolidation. Many of these fractures are not firmly united in the accepted period of three or four months, and if immobilization is discontinued at that stage, union may never go on to consolidation. The imperfectly calcified callus cannot withstand the trauma of movement, and it undergoes decalcification with resulting non-union. If it were reasonable to continue the use of a Whitman plaster for a sufficiently long period, it is possible that most high fractures of the neck of the femur would unite despite the mobility which is permitted. But there is a limit to the endurance of old and fragile patients. The Smith-Petersen nail, on the other hand, may be retained for an indefinite period without hardship; the fact that it affords absolute immobility, and that the immobility is continued for a sufficiently long period, accounts for the difference between bony union in 100 per cent. of cases by this method and in 50 per cent. by the old Whitman method.

INTRA-ARTICULAR ARTHRODESIS OF THE OSTEOARTHRITIC HIP

It is remarkable that the analogy between union of fractures of the neck of the femur and consolidation after arthrodesis of the hip-joint has never been drawn. It is generally recognized that high fractures of the neck of the femur only unite in about 50 per cent. of cases if a plaster spica is relied on for immobilization. It is also recognized that after intra-articular arthrodesis of the osteoarthritic hip only 50 per cent. of cases consolidate. Wherein lies the difference? It is exactly the same problem—the problem of preventing rotational movement of the fragments. If a Smith-Petersen nail is driven through the neck and head of the femur into the pelvis, every such arthrodesis undergoes firm consolidation, and there is no necessity for the complication of an extra-articular graft. The method has been employed in sixteen cases without failure of consolidation in any.

NON-UNION IN FRACTURES OF THE LOWER SHAFT OF THE ULNA

In fractures of the lower shaft of both forearm bones non-union is commonly seen in the ulna, but is practically never seen in the radius, despite the fact that the injuries were sustained simultaneously, and that their treatment was apparently identical. There is no difference in the blood supply of the bones or in their nutrition. Why should one surgeon in the last four years have operated on fourteen cases of ununited fracture of the lower shaft of the ulna, when in every case the radius had united without difficulty? The explanation lies in the fact that pronation and supination of the forearm is a bucket-handle movement of the radius round the fixed axis of the ulna. During the seven or eight weeks which is usually considered an adequate period of immobilization both fractures undergo some degree of union; at the same time the inferior radio-ulnar joint becomes stiff. After removal of the splints or plaster, massage is usually instituted, and an attempt is made to restore radio-ulnar movement. But this movement can occur just as easily at the unconsolidated fracture of the ulna as at the stiffened radio-ulnar joint. The treatment resolves itself into frequent torsion strains of the ulnar fracture, causing traumatic hyperaemia, and therefore decalcification of the callus and non-union. In the radius, on the other hand, both fragments swing together, there is no rotatory strain, and the callus continues to calcify until union is consolidated.*

When these fractures are treated from the beginning in forearm gutter splints or a short below-elbow plaster cast (even though it be unpadded) it is obvious that non-union of the ulna is still more inevitable. Although such a plaster prevents any angulatory displacement it does not prevent rotatory movement of the fragments. The fracture is not immobilized unless there is absolute limitation of radio-ulnar movement by complete fixation of both wrist and elbow. Moreover, this absolute immobility must be continued for three or four months until there is radiographic evidence of consolidation. With such treatment non-union is never seen.

Even after a successful bone-grafting operation complete immobility must be maintained for several months. Two cases which were grafted several years ago were immobilized for ten weeks. The complete plaster was then replaced by a short cast which prevented angulatory movement, but did not completely limit radio-ulnar movement. In the first case subsequent radiographs showed progressive decalcification of the graft at the level of fracture with recurrence of non-union. In the other, the graft fused firmly with the distal fragment, but the callus between the graft and the proximal fragment decalcified and non-union persisted. In both cases after re-grafting, and in all of the other twelve which have been grafted, firm bony union was secured after several months of immobilization. The duration of immobilization was never less than fourteen weeks; in the last case recalcification was so slow that immobility was maintained for eleven months, and there can be no doubt from the radiographs that if movement had been allowed at any time earlier than this non-union would have recurred.

NON-UNION IN FRACTURES OF THE SHAFTS OF OTHER LONG BONES

The same relation of a stiffened joint to an unconsolidated fracture is seen in fractures of the lower shaft of the humerus. Not infrequently, in the treatment of this fracture, rotation movement is incompletely controlled and union is delayed. But the elbow-joint rapidly stiffens, and if attempts are made to restore mobility to the joint

* The position is exactly analogous to that of the fractured rib, where with every respiration both fragments move together but not on each other. The intercostal muscles and aponeuroses provide a natural protection from shearing and rotatory strains.

by passive movement the fracture is strained and non-union persists. Incidentally this is merely one of the complications which are directly attributable to passive movement of the elbow-joint—a procedure which cannot be defended on any grounds.

Non-union is quite frequently seen in fractures of the shaft of the femur when a Thomas splint has been ineptly used, so that the extension tapes have rarely been tight and the limb has been allowed to twist and angulate within the splint. The non-union may persist for months, and yet as soon as adequate nursing is available, so that the extensions never slacken even momentarily, the fractures unite.

The belief that the rate of union of a fracture is determined only by its site, and that the correct treatment is to immobilize for a certain number of weeks and then to institute massage treatment, is responsible for many cases of non-union. It is a stock examination question to ask a candidate how long he would immobilize a fracture of the shaft of the tibia, and there can be no doubt that he would receive little credit for the correct reply: "Until it is united." The rate of union varies very considerably in different individuals, and although many fractures unite in eight or ten weeks, it may be several months before union is consolidated. If at any time before the fracture is clinically firm, absolute fixation is interrupted, even by the substitution of walking splints for the complete plaster, union is delayed. If sufficient mobility is allowed the soft callus undergoes decalcification, and in the course of time the fractured surfaces become sclerosed with establishment of non-union.

INFECTED COMPOUND FRACTURES

The infected fracture is exactly like the simple fracture, except that the hyperaemia of infection is added to the hyperaemia of injury, so that decalcification is more marked and continues for a longer period. A wide gap may appear between the fragments, but the space is only apparent, and, like the "cyst" in the old fracture of the scaphoid, it is filled with granulation tissue which will recalcify after quiescence of the infection. If perfect immobilization has been maintained by the Winnett Orr no-dressings-plaster method the fracture will unite. If, on the other hand, the treatment of the infection is allowed to interfere with the immobilization, the fracture fails to unite. The application of the Winnett Orr method is of far greater importance in the treatment of infected fractures than in the treatment of osteomyelitis. However committed the fracture may be, however serious the infection, and however extensive the destruction of skin, the use of this method avoids the necessity for amputation in almost every case except that in which the main artery is injured.

It is in the terminal stages of the infection that immobility is of the greatest importance. Even if the fracture is already several months old, and if there are still sinuses with sequestra between the fragments, it is obvious that the gap is filled with hyperaemic granulation tissue which has not yet undergone fibrosis. In such a case, after simple sequestrectomy *unaccompanied by any scraping away of the valuable granulation tissue*, the application of a Winnett Orr plaster will usually determine union of the fracture in three or four months. If, on the other hand, the infection has already recovered and the sinuses have healed without the fracture having been immobilized, the granulation tissue has undergone fibrosis and the fragments are sclerosed. It is now useless to immobilize the fracture without first freshening the surfaces, either by multiple drilling or by bone grafting.

If after such a refreshing operation there should be a recurrent flare of infection, it does not by any means

follow that the operation will fail. The flare of infection will itself produce the hyperaemia and decalcification which is a necessary preliminary, and if the fragments are immobilized while the infection subsides the fracture will usually unite.

CONCLUSIONS

1. Non-union of fractures is almost always avoidable, and is a complication entirely within the control of the surgeon.

2. Many physiological and biochemical factors may be concerned in the rate of union of fractures, but the only one factor which is of practical importance in determining non-union is inadequate immobilization. Immobilization may be adequate in two ways. (1) The fracture is allowed movement within the splints or plaster; rotatory movement is especially inimical to union. (2) Immobilization is not continued for a sufficiently long period. There can be no fixed period of immobilization for any fracture; the average duration of immobility may be exceeded in occasional cases by many months.

3. Hyperaemic decalcification and ischaemic recalcification of bone must be accepted as pathological facts. The initial traumatic hyperaemia mobilizes calcium salts from the bone ends, but rapidly subsides, and allows recalcification of the young connective tissue to form callus. With final repair and fibrosis the callus consolidates by increased calcification. If the hyperaemia is perpetuated by the trauma of movement there is excessive decalcification—a crack fracture becomes a gap fracture. This is the first stage of non-union. In the final phase of ischaemic fibrosis the surfaces of the fragments undergo sclerosis; this is the second stage of non-union. The two stages of non-union are distinguishable radiographically. The first is cured by immobilization. In the second, preliminary revascularization is necessary by a drilling or grafting operation.

4. The infected compound fracture is pathologically similar to the simple fracture, except that the initial stage of decalcification is prolonged. If it is immobilized the fracture will usually unite. An old infected fracture which has not been immobilized is in the first stage of non-union so long as the infection is active, but passes into the second stage of non-union after quiescence of the infection. In the first stage, sequestrectomy without "scraping," followed by immobilization, determines union. In the second stage a revascularizing operation is necessary. Even if the operation is followed by a flare of infection the fracture still unites if it is immobilized.

E. A. Fennell (*Journ. Amer. Med. Assoc.*, April 7th, 1934) states that at irregular intervals during the last ten years sporadic cases clinically resembling typhoid or paratyphoid fever, but with persistently negative laboratory results, have been reported in Honolulu. The symptoms consisted in a prodromal period; rather sudden onset; rose spots of exaggerated character on chest, abdomen, and inner aspect of the arms and thighs; headache; cough; and fever. McCoy's suggestion, in 1932, that these might be cases of typhus fever was confirmed by a positive Weil-Felix reaction. Up to date ten cases of endemic typhus have been detected in Honolulu. It differs from epidemic typhus, first, in being essentially a disease of rats, transmitted to man by the flea; secondly, in being a disease of the summer and autumn (whereas epidemic typhus is a disease of winter); and thirdly, by its very low fatality rate.

HYOSCINE AMNESIA IN LABOUR

AN ANALYSIS OF FIFTY CASES

BY

TREVOR BARNETT, M.D., F.R.C.S.

SOUTHEAST

The use of hyoscine during labour was first brought to my notice in a paper by Jennings (*British Medical Journal*, November 2nd, 1929), in which a series of twenty-four cases was reviewed. The method is attributed by him to Dr. Bertha Van Hoosen of Lyola University, U.S.A., who, working on the suggestion that morphine used in the usual twilight sleep technique was responsible for the oligopnoea and asphyxia of some of the newborn, developed a technique in which hyoscine alone is used for the production of amnesia.

The drug used is hyoscine hydrobromide, and it is given by hypodermic injection. The Burroughs Wellcome tablets of 1/100 grain have been used.

NUMBER OF INJECTIONS AND DOSAGE

At the commencement of treatment three injections of hyoscine 1/100 grain are given at half-hourly intervals, and a further dose of 1/100 grain is given two hours later, and repeated every two hours until the termination of the second stage. In many cases the initial three doses are sufficient, and they are given without regard to the age or weight of the patient. The effect of the first injection is slight, and the actual injection is always remembered by the patient. After the second injection, in some few susceptible patients, semi-coma develops, the woman sleeping deeply between the pains, and only stirring slightly during contractions. In such cases the third injection is omitted. The vast majority still complain after the second injection, and a third is then given. In this series of fifty cases no patient received less than three injections. After the third injection amnesia is well developed in most cases. Many patients remember being given the second injection, but they are all oblivious of the third. When fully under the influence of hyoscine the patient sleeps quietly in the intervals between the pains. During the contractions she wakes up, moves the legs and arms, sometimes talks incoherently, but does not cry out. At any time she can be roused sufficiently to open her eyes, but cannot answer simple questions. If she can carry on a conversation, or if she cries out with the pain, a further injection is required.

The state of obfuscation begins to wear off about two hours after the last of the three injections. At this time the patient will begin to complain of the pains; she will cry out and will be able to answer questions put to her. The fourth injection is then necessary. In most cases delivery has been effected before a further lapse of two hours, but if this is not the case a further injection may be given if the signs of returning awareness appear. In this particular series a fourth injection was given in eighteen cases. In no case in this series was a fifth one necessary, although in cases not here included I have given up to seven injections.

WHEN TO COMMENCE TREATMENT

It is essential that uterine contractions should be occurring regularly and with some strength before hyoscine is given. The cervix must be taken up, and should admit two fingers. Hyoscine is not given whilst an elongated cervix can be felt.

As soon as pains are occurring with regularity and with ten to fifteen-minute intervals, a rectal or vaginal examination is made. If the cervix is effaced, and if the os

admits two fingers, the injections of hyoscine are commenced. If the cervix is not effaced chloral and bromide are given if the patient is complaining. If the cervix is effaced and dilated but pains are absent or infrequent an enema, or quinine 10 grains, is given, and as soon as good pains commence the hyoscine is started.

No distinction has been made between primiparae and multiparae, the indications for commencing the injections in both cases being the regular occurrence of pains, the effacement of the cervix, and commencing dilatation.

COURSE OF LABOUR

An important feature of the amnesic labour is the absence of the bearing-down efforts of the patient during the second stage. This absence of the action of the abdominal muscles does not retard the labour seriously, if at all, though the point is difficult to determine. Owing to the absence of visible bearing-down efforts it is difficult to tell from observing her whether the patient is in the first or second stage of labour, and unless frequent examinations are made the onset of the second stage will not be appreciated.

In this series of cases examinations, usually rectal, have been made to determine the state of the cervix before giving the initial injection of hyoscine. In many cases no further examination has been made: in others the descent of the head has been followed by one or more further examinations. These can always be made satisfactorily by the rectum, and only if in doubt as to the state of the cervix or the position of the presenting part in cases of delayed descent need a vaginal examination be made.

DURATION OF LABOUR

It has been observed that under hyoscine amnesia the total duration of labour is somewhat lessened (Jennings). In this series of cases it was not possible accurately to obtain the exact time of onset of labour. Instead, the duration of labour after the initial injection of hyoscine has been measured. It has not been found to be unduly long. The interval between the initial injection and the termination of the second stage in forty-seven cases was found to average 5.4 hours in primiparae and 4.5 hours in multiparae. The actual intervals were as follows. In thirty-two primiparae four cases were completed in three and a half hours or less, seven in over six and a half hours, whilst the majority, twenty-one, fell between four and six hours. In multiparae six were completed in three and a half hours or less, one took seven hours, whilst eight were between four and six hours.

These times represent the duration of labour after two-finger dilatation of the effaced cervix—that is, the time taken for the termination of the first stage and the whole duration of the second stage of labour. It was not deemed expedient to make the necessary examinations in order to determine accurately the duration of the second stage, but these figures clearly indicate that there is no serious delay in labour, if in fact there is any delay at all.

THE THIRD STAGE

There is no ill effect on the third stage nor is there any effect on the post-partum loss. In two cases the duration of the third stage was not noted; in one case the placenta was adherent and manual removal was necessary. In the remaining forty-seven the time varied from five minutes to thirty-five minutes, the majority being about fifteen minutes. In thirty-seven cases the duration of the third stage was between fifteen and twenty-five minutes, in three between five and ten minutes, and in seven between twenty-five and thirty-five minutes.

It was not found practicable to measure accurately the total amount of post-partum loss, but in no case was this excessive, nor did it differ from what experience has led one to expect after any normal labour.

RESTLESSNESS

The only drawback to the more general application of the method is the restlessness which occurs in about half the cases.

In this series twenty-three cases were restless, the symptoms varying from simple agitation during the pains to more decided efforts to get off the bed. The remaining twenty-seven cases were quiet, showing little reaction, except slight movements during pains. Of the restless cases three were very restless. In none of the cases did restlessness extend beyond the pains, all lapsing into somnolence during the intervals. These patients may cry out, kick, sit up, endeavour to get off the bed or to stand up, and they are very troublesome. The percentage of these very difficult cases is small. They require the time of two nursing attendants. The great majority of those classified as restless are easily controlled by one nurse. Of the twenty-seven quiet cases ten were very quiet, barely evincing evidence of the pains, and being comatose in the intervals.

There is no means of ascertaining which patients may be expected to be quiet and which restless. A nervous or hysterical patient may be most favourable, whilst a more stolid individual may give considerable trouble. The depth of amnesia is not affected by the behaviour of the patient, the very agitated and difficult cases being completely unaware of the trouble they may have caused. As mentioned, in this series of fifty cases, twenty-seven were quiet, twenty were restless and required active restraint, whilst three necessitated the presence of two nursing attendants for some hours.

THE PUERPERIUM

The puerperium was normal in forty-seven cases. Two cases developed recrudescence of pregnancy pyelitis, but in both cases, as the pyelitis had been present during the eighth and ninth months, this was to be expected, and does not mean that pregnancy pyelitis is a contraindication to the method. One case developed puerperal mania, but here again the history was one of mental instability with two previous nervous breakdowns. During labour the pupils are widely dilated and remain so for some hours after delivery. Vision is blurred from paralysis of accommodation, but returns to normal within a few hours, the time varying with the amount of hyoscine given and the duration of somnolence after the labour.

Much has been written concerning the occurrence of terrifying nightmares after morphine-scopolamine narcosis. In my experience this is not true of hyoscine amnesia. The only two cases I have met with of unpleasant dreams after labour have been in two rather highly strung cases, and even these were not bad.

NEED FOR ADDITIONAL ANAESTHESIA OR FORCEPS DELIVERY

In twenty-two cases no other anaesthesia was necessary. In the remaining twenty-eight chloroform was given during delivery of the head. This additional anaesthetic is given rather to prevent restlessness than to alleviate pain. The twenty-eight cases in which additional chloroform was given included eight in which forceps were applied, and one case of delivery of the after-coming head. Of those receiving no other anaesthesia fifteen were quiet and the remaining seven restless. Of those receiving chloroform thirteen were quiet and fifteen restless. Two

cases were delivered by forceps without additional anaesthesia.

Owing to the non-participation of the patient during the second stage, the conscious bearing-down efforts are, as already stated, not present under hyoscine, though their absence has little effect on the descent of the head as far as the perineum. Descent may be aided to some extent by pressure exerted on the fundus during the pains. It has been my practice, if any delay occurs after the scalp can be seen at the vulva, to expedite the final stages by applying forceps. This has been done more particularly in the restless cases. In this series of fifty cases forceps delivery was necessary in ten. In seven of these low forceps were applied to help the head along the perineum. The remaining three included two cases of persistent posterior occipital rotation, and one of generally contracted pelvis. The instrumentation rate is thus low, and were it considered undesirable to apply low forceps at the termination of labour the figure could have been kept lower still.

EFFECT ON THE INFANT

Of the fifty infants two were stillborn. Of these, one was a post-mature foetus, presenting as a breech with extended legs and arms, and the other was a premature foetus (thirty-five weeks) with imperforate anus. The final injection of hyoscine had been given three hours before delivery in this latter case. A premature baby (thirty-six weeks) lived only eight hours. The last dose of hyoscine was given five hours before delivery. Of the remaining forty-seven babies one was noted as being blue at birth, and this was a thirty-fourth-week baby weighing 4 lb. 8 oz. It rapidly recovered and did well. In this case hyoscine had been given four hours before delivery. The remaining forty-six babies were normal in all respects, crying lustily at birth, and showing no signs of asphyxia or apnoea. It can definitely be stated that hyoscine, as given above, has no ill effect whatever on the foetus, even when given a short time before delivery. In this series the shortest interval between the last dose of hyoscine and the time of delivery was thirty minutes.

DURATION OF AMNESIA

Patients remember the first injection, sometimes the second, but never the third. The total duration of amnesia was between four and six hours in thirty-seven cases, below four in five cases, and above six in eight cases. In twenty-three cases there was no recollection of any event from one and a half to two hours before delivery; in twenty-two the amnesia extended back from three to five hours; in four amnesia was for one hour before delivery, and in one case for half an hour only, but in this case the third injection was given forty minutes before the child was born. In all cases there was no memory of the actual delivery, and amnesia extended for some hours afterwards.

The amnesia after delivery persisted for from one to two hours in forty cases, and in the remaining ten it was between three and five hours. That is, it was not until from one to five hours after the birth of the child that the patient awoke to the realization of her surroundings. The patients appear well and smiling, and are generally incredulous when they learn that the baby has been born. The most striking feature is their fresh and smiling appearance a few hours after delivery, compared with their flushed and often somewhat dishevelled appearance during the labour, and if one is inclined to abandon the method during the conduct of a particularly obstreperous labour, one is amply repaid by the sight of the placid, smiling patients, who have no knowledge of the trouble they may have occasioned.

CONCLUSIONS

It may be stated that hyoscine amnesia in labour has in my hands proved an entirely safe method, as regards both the mother and the child. Labour is not delayed, puerperal morbidity is not increased, and the babies are born without circulatory or respiratory defects. Amnesia is absolute, and covers a period including the whole of the second stage of labour. There have been no fatalities nor accidents attributable in any way to the hyoscine.

The only disadvantages are the need for constant supervision during the labour, and the occasional necessity for two nurses to control the patient. I do not wish to minimize this difficulty, as it is a real one, and the only serious objection to a more general use of the method. It may, however, be emphasized that restlessness occurs in less than half the cases, and is only of serious degree in a small minority—three cases in this series of fifty.

I have never adopted hyoscine amnesia in domiciliary midwifery, and would not do so unless I could be assured of the presence of the possibly necessary skilled assistants. I consider that the best results will always be obtained when one has the assistance of a nursing staff who are thoroughly acquainted with the details of the treatment. The cases in this series have been consecutive and were treated in one nursing home with a constant nursing staff.

SOME OBSERVATIONS ON THE SYMPATHETIC NERVOUS SYSTEM*

BY

E. R. FLINT, F.R.C.S.

SURGEON TO THE GENERAL INFIRMARY AT LEECS

The sympathetic nervous system and the parasympathetic make up the autonomic nervous system, with which the endocrine glands are in close association. I would, at first, like to call your attention to one or two facts which indicate that the sympathetic system is anatomically arranged to give a widespread physiological effect on stimulation, and that all its diverse activities are co-ordinated to produce in the body the response required to meet most favourably circumstances arising at any particular moment. The bilateral ganglionated cord of the sympathetic system reveals a ganglion for each segmental area of the body (except in the cervical region, where fusion has reduced the number to three); from each ganglion sympathetic fibres proper are carried to each of the spinal nerves by the grey rami for distribution to the somatic areas. The connexions of the ganglia to the cord, however (named white rami), are confined to the dorsal and upper lumbar spinal segments, and each of the fibres making up the white rami synapse with several cells in the sympathetic chain, so that a generalized body effect is produced by stimulation passing out of the cord in a comparatively restricted area. The splanchnic nerves spread their impulses widely in a similar way to the viscera. Moreover, there is a central control situated in the hypothalamic region at the base of the brain, which is, in turn, influenced to some extent by the cortex.

Woollard and Norrish (*Brit. Journ. Surg.*, 1933, xxi, S3) say: "It is to be inferred that the autonomic system as a whole appears comparatively late (in development), and of its three portions the sympathetic system (keeping this term for the thoraco-lumbar outflow) is the last of all to appear." Another feature in development which seems to run parallel with the perfecting of a sympathetic system is the independence of the organism of vagaries in its external environment. This is accomplished by a mechanism for keeping constant the internal environment in all

the many conditions which are always tending to its variation, and the co-ordination of the components of this mechanism are apparently controlled by the sympathetic system and its closely associated allies. The more urgent the demand on this mechanism the more does it seem to be controlled by the sympathetic nerves. In quiet conditions, presumably, the endocrine glands are sufficient protection, since it has been shown by Cannon that the whole of the peripheral ganglionated cords of the sympathetic system can be removed in an animal; and, provided it is not exposed to great variations in temperature or to any other condition which might demand a struggle for existence, it can live comfortably and without difficulty.

If one keeps in mind this fundamental purpose of the sympathetic nervous system it is easy to understand its apparently contradictory action on tissue of the same character: for example, stimulation by strong emotions causes constriction of the unstriated muscle of the peripheral vessels and relaxation of the unstriated muscle of the intestine and bronchioles, the object being to force blood into such important organs as the brain and the heart, to conserve energy which would otherwise be expended on intestinal activity—for the moment wastefully—and to ensure a freer supply of air to oxygenate the rapidly moving blood. Moreover, the spleen is contracted, whereby a large number of red cells are forced into the circulation to carry an increased supply of oxygen to the hyperactive tissues, where rapid oxygenation is essential; and sweating (another sympathetic function) dissipates the heat so engendered, which would quickly become dangerous if not eliminated. I want to emphasize this aspect of the sympathetic system, because surgery has become rather busy with it in recent years, and the localized nature of the operations is apt to make us rather forgetful of the generalized activities of the sympathetic, with which surgery has had little to do as yet.

The chief conditions for which operations have been performed on the sympathetic nerves can be arranged under four headings: (1) vascular; (2) secretory; (3) dysfunction of unstriated muscle of hollow viscera; and (4) certain painful conditions.

ACTION OF SYMPATHETIC NERVES ON VESSELS

The predominating effect of the sympathetic nerves is constriction of the vessels. The more unstriated muscle in the wall the more is the vessel influenced by the vaso-constrictors; consequently the large vessels are little affected, whereas the small arteries can be constricted to the point of complete closure. Section of the vaso-constrictors releases the vessel from its normal tonicity, and dilatation results. It is not known whether there are vaso-dilator fibres to the vessels; if there are, they are probably parasympathetic in origin, and take the same peripheral course as the sympathetic nerves—that is to say, run in the ordinary spinal nerves and innervate the vessels by branches distributed as they pass along the limbs. A limb deprived of its sympathetic supply becomes hot and, at first, rather red, and sweating cannot be induced by normal means. In the course of a few days the redness lessens and the extremity becomes rather paler than the normal side; this is said to be due to the capillaries regaining some tone. The blood, however, still flows more quickly, and the part remains permanently warmer than the other side.

Raynaud's Disease

This being the case it seemed reasonable to expect sympathectomy to be beneficial in conditions which are obviously due to vasospasm, the typical example being Raynaud's disease. This is a paroxysmal, bilateral vasospasm of the digital arteries provoked by cold or emotion in certain subjects, and in severe cases it goes on to

* An address delivered to the Nottingham Medical Society.

superficial necrosis or loss of the terminal parts of the digits by a process of dry-gangrene. But it soon became obvious that the vessels in Raynaud's disease do not behave in quite the same way after sympathectomy as they do in normal cases. The immediate response is the same, but if, very soon after the operation on the upper extremity, the hands be cooled for twenty minutes in water at 15° C. in a constant room temperature of 18° to 20° C. and the rest of the body be then heated to 40° C. with the dried hands lying exposed, it will be found that the surface temperature of the normal hands very quickly rises to the maximum of 32° to 34° C.; whereas in Raynaud's disease there is a longer latent period before the rise begins, though thereafter it rapidly goes on to the same extent. Six to nine months later the same experiment shows that the normal vessels respond to heating better than those in a patient with Raynaud's disease, but in neither case is the response so marked as it was just after operation. According to Lewis, Raynaud's disease depends on a local fault in the small arteries, and this explains why it is possible to induce cyanosis by immersing the hands in cold water in all cases of the disease after sympathectomy, since the operation does not cure this local defect. But why should not the limb with normal vessels respond fully to heating after it has been sympathetomized? No doubt a recovery in tone accounts for this in part, but in order to get a completely satisfying explanation it seems necessary to assume that sympathectomy interrupts dilator as well as constrictor fibres to the vessels.

Theoretically, therefore, the ultimate benefit to a patient with Raynaud's disease would appear to be doubtful; experience demonstrates, however, that such a patient actually gains a great deal. The majority of cases do not develop cyanosis after sympathectomy so easily as before; the attacks are shorter; they are not painful; the functional capacity of the digits is increased; and the liability to ulceration is removed. A small number of patients receive little or no benefit; they are found among the advanced cases with sclerodactyly and marked ulceration or gangrene—that is to say, organic changes have been superimposed on the spasm. There is a curious difference between the upper and lower limbs: in the latter the results are said to be always good, the failures being confined to the upper limb. The greater difficulty of the operation and the greater variability of sympathetic distribution in the latter case do not seem to me to be the full explanation, though it is the one usually given.

Acrocyanosis: Thrombo-angiitis Obliterans

Acrocyanosis is another disorder which reacts to sympathectomy in the same way as Raynaud's disease, and for similar reasons. The principle underlying this operation is an improvement in the blood supply, and in this respect it conforms to that of the usual medical methods—such as massage, radiant heat, counter-irritation, and so on; but, whereas the latter are intermittent and have to be repeated, sympathectomy seeks to produce its effects once and for all. The usual methods should be tried first, but it must be kept in mind that sympathectomy gives its best results in cases which have not been allowed to progress too far. Where organic obstruction to vessels is present removal of constrictor fibres can offer little or no useful prospect, and that is why the operation has had only a limited use in such diseases as thrombo-angiitis obliterans. This is a progressive disease, mainly of the lower limbs, in which the larger arteries become slowly obliterated; it is painful, and may be accompanied by intermittent claudication. The ultimate result is usually gangrene requiring amputation, but in some cases the disease is arrested spontaneously. Sympathectomy will abolish pain (except that due to claudication, which it

only lessens); but whether it will improve the blood supply can only be determined by preliminary tests—tests which should normally produce vaso-dilatation. These are heating the body, local anaesthesia of the main nerve trunks or of the appropriate sympathetic ganglia, spinal anaesthesia in the case of the lower limbs, and protein shock phenomena induced by the intravenous injection of triple typhoid vaccine. Should one or other of these tests show that no vaso-dilatation can be obtained in the affected limb, or only a rise of 2° or 3° C., the operation is contraindicated. A bigger rise in temperature affords ground for hope that sympathectomy will at least retard the disease, and, as it is usually bilateral and generally progresses to gangrene, this is a gain; but there is evidence that the value of the operation extends even to that of a curative effect. I have had little success in these cases, because they have mostly been late ones; but in two there has been no evidence of advance during twelve months since the operation.

There are many diverse conditions in which a better blood supply would be of benefit to the tissues, and if it can be shown that sympathectomy is able to effect this the operation should be considered: such are chronic ulcerations of many kinds, and recurrent chilblains and ulceration in limbs afflicted with the results of anterior poliomyelitis (I have had one very successful case of this type). There is a possibility that better knowledge of the anatomy and physiology of the sympathetic system may open up eventually a much bigger field for the operation. So far I have seen no real ill effects following limited interference with sympathetic innervation.

SYMPATHETIC NERVES AND SECRETIONS

Sympathectomy permanently abolishes sweating due to natural causes over an area which accurately delineates the sympathetic supply. This is so definitely established that it is a useful sign as to whether complete division of the sympathetic supply has been accomplished. I have had only one case of excessive sweating in which I have had the opportunity to perform the operation. This was that of a young man of 26 in the Salvation Army. The fervour generated in the course of his work caused sweat to pour down the left side of his face, the right being only normally moist. I removed the superior cervical sympathetic ganglion and his face remained perfectly dry for the time he was under my observation. This was done three years ago. I recently had a letter from him from the Sandwich Islands, to which locality he has been transferred, in which he says that the left side of his face still remains dry, and he is highly satisfied with the result.

Probably a wider application for the operation will be found in those unfortunate people—usually excitable females—who suffer intensely from moist, clammy hands and feet. The feet, particularly, in these cases become sodden, fissured, painful, and offensive: these can be relieved at once and quickly cured by sympathectomy.

DERANGED FUNCTION IN HOLLOW VISCERA

Functional derangements of the bladder, ureters, and colon are those for which sympathectomy has been most often performed. I shall confine my remarks to the colon. The action of the sympathetic system here is inhibitory, except at the sphincters, where it causes contraction; the parasympathetic system has the reverse action. It is assumed that overaction of sympathetic or diminished activity of parasympathetic nerves is responsible for certain irregularities of bowel function, and in either case sympathectomy permits more effective peristaltic efforts of the colon.

Hirschsprung's Disease

In Hirschsprung's disease no medical treatment alone is satisfactory, and hitherto effective surgical intervention

has been accompanied by too serious a risk; but in sympathectomy we have undoubtedly a safe and efficient method of attack. The bowels act from the first without enemata, whereas these were necessary before; the abdominal distension becomes much less; the general well-being is immensely improved; and by x-ray examination it is seen that haustrations appear in the sac-like colon, which was present before operation. The operation should be done in childhood because the hypertrophied colon gradually develops a good deal of fibrous tissue in its wall; and as in the case of the vessels, so in that of the colon, such organic change cannot be rectified by sympathectomy. Moreover, it is a mistake to think that surgery is all that is needed: there is always a tendency to relapse, which can only be prevented by re-education of the bowel muscle by careful medical attention.

Chronic Constipation

As such excellent results followed sympathectomy in Hirschsprung's disease it was perhaps natural that surgeons should have turned their attention to its effect on chronic constipation. This is a subject bristling with difficulties, and so far it is not easy to be sure of the proper place surgery should take. Hitherto many surgical procedures have had their day and passed into desuetude. Sympathectomy may share the same fate. I think it almost certainly will, when we understand better the chemical phenomena which lie at the root of unstriped muscle response. In the meantime the results as a whole are encouraging; the operation is without any greater risk than attaches to any simple intra-abdominal procedure; and the only ill effect which may occur seems to be a relapse into the pre-operative state. The main difficulty, in my opinion, is selecting the right case. The first essential is the failure of medical treatment materially to relieve the chronic ill-health which sometimes accompanies irregular and infrequent action of the bowels. The second essential is, I think, the state of the colon as revealed by x-ray examination: there should be some distension, absence of well-marked haustrations, and apparent increase in length of the colon. These are the signs one would expect to see with inhibition; the reverse would indicate spasticity, and would presumably not be improved by sympathectomy. In the type of case I have indicated there is no question as to the immediate results being good, even dramatic: patients who have had no action of the bowels for days, and then only with huge doses of aperients or not without enemata, begin in two or three days after operation to have the bowels moved without other artificial help; they gain in weight, improve in complexion, and later get back to work, which they may have had to give up; they also lose the abdominal discomfort, sometimes amounting to pain, which so often accompanies their pre-operative state. There is, however, a decided tendency to relapse in the course of six or twelve months; but, even so, the majority of patients are better off than before. I am sure, from my experience, that careful medical supervision after operation delays this tendency to recur; and improper selection of cases is another reason for relapse. It may be, too, that further experience of the path of sympathetic impulses will show that operative procedure can be improved.

I have performed sympathectomy on sixteen patients with chronic constipation of the kind I am describing. In answer to inquiries I have had no reply from two; in two the results have been poor, the patients having relapsed into their former condition; in two, large doses of aperients, but not enemata, are required, but both say they feel much better generally; six of the remaining ten have daily action of the bowels without any aperient,

have no abdominal pain, and feel very well. Three of these patients were operated on in 1931 and three in 1932. Here is a letter from one of the former: "I should like to say my operation was a success; my bowels work regularly from day to day, I never have any pains, and I am stronger and better in health than ever before in my life." The others write in a similar strain. Four of these ten cases have been operated on too recently to be sure of the ultimate result. There have been no fatalities.

CERTAIN PAINFUL CONDITIONS

The association of the sympathetic system with pain is confusing. As regards the viscera there is no great difficulty. Pain is caused by abnormal tension on the muscle fibres in the hollow viscera, and probably by stretching of the fibrous capsule in the case of the solid organs. The only afferent pathway from the viscera is via the sympathetic nerves, though the ultimate entrance into the central nervous system is supposed to be by the posterior spinal roots. Sympathectomy, therefore, must interrupt the afferent fibres. But in the case of the limbs it is different. The sympathetic fibres run in the ordinary somatic nerves, not as separate trunks, as in the case of the splanchnics; and if they enter the spinal cord through the posterior roots, as they are said to do, there is no means of interrupting them apart from section of the peripheral nerve trunks. Nevertheless, sympathetic ganglionectomy, which does not interfere with these trunks, undoubtedly abolishes certain types of pain in the limbs. The pain which can be so influenced is of the ill-defined, rather widespread, and usually burning type, which Head called protopathic, and which seems to arise—sometimes at any rate—in the walls of the vessels. Sympathectomy, therefore, may abolish pain indirectly by an efferent effect, having nothing to do with the afferent impulses—or our supposition that the afferent fibres pass directly by the posterior roots, avoiding the sympathetic ganglia, may be wrong. There is a third possibility—namely, that pain fibres pass up the network of nerves which surround the vessels, in which case they would ultimately reach the sympathetic ganglia. The most dependable evidence favours the first view. It is assumed that the pain experienced in Raynaud's disease is caused by spasm of the small arteries, or by the collection of irritating metabolites in the capillary areas beyond the spasm; in either case sympathectomy should, and does, relieve the pain by causing vasodilatation.

Causalgia

I have had five cases of causalgia in which the patient has been instantly relieved of the excruciating pain experienced before sympathectomy, and probably for the same reason as applies to the cases of Raynaud's disease. Whatever the real explanation, this method of treatment is so effective that it should entirely displace the crippling operation of median or ulnar nerve excision, which is carried out by some surgeons with the object of intercepting the pain fibres, and in the hope that, when regeneration ultimately occurs, the pain will not return.

The paroxysmal attacks of pain so characteristic of trigeminal neuralgia suggest very strongly what one notices in causalgia, and it was for this reason that I removed the right stellate ganglion in an elderly woman suffering from a severe manifestation of this complaint. This was done eighteen months ago, and was followed by instant relief of pain: on inquiry during the last fortnight her doctor tells me she has had no return of it, and he considers her cured. The dangers of injury of important structures at operation are as nothing compared to those associated with direct attacks on the Gasserian ganglion or its roots, and if further experience substantiates its effectiveness this procedure will be a very distinct gain.

THE INFLUENCE OF EMULSIONS OF OILS AND FATS UPON THE ACTION OF BACTERIAL TOXINS

BY

G. NORMAN MYERS, M.D., Ph.D., M.Sc., A.I.C.

LEIT MEMORIAL RESEARCH FELLOW

(From the Pharmacological Laboratory, Cambridge)

Investigators now are generally agreed that certain bacterial toxins, when absorbed into the circulation, are capable of producing fatty degeneration in tissues. In this way the heart, kidneys, liver, adrenals, and central nervous system may be profoundly affected.

Numerous workers¹⁻¹¹ have reported that diphtheria toxin, in particular, may cause widespread damage to cells of the body in this way. While investigating this problem in the summer of 1929 I examined several hundreds of hearts taken from guinea-pigs, rabbits, and cats which had succumbed to the lethal effects of diphtheria toxin. The regularity with which fat is laid down in cells in response to injury by this toxin led me to carry out a number of experiments with a view to finding whether fats exert any protective influence against the destructive effects of toxins. The original idea was that the fat deposited in the cell might act as a protection against further damage to the cell. A few experiments, using various oils and fats, quickly showed that this supposition was ill founded, and that oils or fats in such coarse globules as are found in cells during fatty degeneration have no influence whatever on the lethal effects of the toxins. This, however, led to a series of experiments, using oil emulsions in a very fine state of division, and it is a brief outline of the results of these experiments which is embodied in this communication.

SCOPE OF INVESTIGATION

The object of this work was to determine whether very finely divided emulsions of oils and fats have any modifying effect upon the action of bacterial toxins. Oils and fats derived from vegetable, mineral, and animal sources were used, and those selected as being the most suitable were olive oil, liquid paraffin, and the cream of cow's milk. Their influence upon the lethal effects produced by the toxins of *B. diphtheriae*, *B. tetani*, *Cl. welchii*, and the *Cl. oedematis maligni* (Koch) was studied.

The oils and fats were made into finely divided emulsions by means of mechanical emulsifiers, and, in certain experiments, an emulsifying agent was added to make the emulsions more stable. Aqueous solutions of the toxins were mixed with the emulsions immediately prior to injection into the animals. The toxins were kindly supplied by Dr. O'Brien of the Wellcome Laboratories, and the emulsions were made by Mr. E. Saville Peck of Cambridge. All the toxins were standardized, using standard animals. An emulsion containing 50 per cent. olive oil and gum acacia as an emulsifying agent was used in the first experiments.

EFFECT OF OLIVE OIL EMULSION

Twelve guinea-pigs were injected subcutaneously with a mixture of 4 m.l.d. of diphtheria toxin in the emulsion. Four guinea-pigs were used as controls, and injected with 4 m.l.d. of the toxin in an aqueous solution, without the addition of the emulsion. All the animals which had been injected with the toxin-emulsion mixture survived, and were fit and well twelve months later. Other experiments, conducted on similar lines, but using 6, 12, and 24 m.l.d., yielded similar results. The volume of the emulsion contained in each injection was usually thirty to fifty times that of the aqueous solution of the toxin, and the total volume injected rarely exceeded 0.5 c.cm.

Three further series of experiments were conducted in a similar way, using the toxins of *B. tetani*, *Cl. welchii*, and the *Cl. oedematis maligni* (Koch) respectively. In every case the results agreed with those using diphtheria toxin, thus proving that if lethal doses of these toxins are mixed with finely divided emulsions of olive oil before injecting them subcutaneously into animals, then such animals do not succumb to the lethal effects of the toxins.

INFLUENCE OF EACH CONSTITUENT OF THE EMULSION

Experiments were then performed to determine the cause of this protection, and the relative importance of the constituents of the 50 per cent. emulsion. The emulsion contained olive oil, gum acacia, and water, and one might conclude that either the oil or the gum may have modified the action of the toxins, or even destroyed them in some way. This might explain the protective action of the emulsion.

OLIVE OIL

The influence of the oil alone was first determined by omitting acacia from the emulsions. This necessitated making a simple emulsion of olive oil with water by means of a mechanical emulsifier. These were mixed with the toxins and injected subcutaneously soon after they had been prepared. The results obtained were very variable. In some experiments the mortality rate of the emulsion-toxin animals was as high as 100 per cent., while in others all the animals survived. This discrepancy was found to be due to the degree of division and stability of the emulsions. The protection afforded appears to be proportional to the degree of fineness of the emulsion. Coarse emulsions afforded no protection against lethal effects of the toxins.

GUM ACACIA

A solution of gum acacia was made so that the concentration of the gum within it was equal to that contained in the 50 per cent. olive oil emulsion. This gum solution was mixed with aqueous solutions of superlethal doses of the toxins immediately prior to injection into animals. Using guinea-pigs, it was found that with 4 m.l.d. of diphtheria toxin all the animals died irrespective of whether they had received the gum acacia or not. Further experiments, using the toxins of *B. tetani*, *Cl. welchii*, and the *Cl. oedematis maligni* (Koch) instead of diphtheria toxin, yielded similar results. It is obvious from this that gum acacia does not modify the lethal effects of these toxins, but simply assists in binding the emulsion together in a more stable form. The protective action of the emulsion is therefore concerned with the fineness of the olive oil globules, while the gum acacia renders the protection more secure by making the emulsion more permanent.

DISTRIBUTION OF TOXIN IN EMULSION

This question was investigated further in another series of experiments. A simple emulsion of olive oil was made in as fine a state of division as possible, using a mechanical emulsifier. The emulsion was mixed with a superlethal dose of diphtheria toxin (8 m.l.d.), and injected subcutaneously into a number of guinea-pigs. A suitable number of control animals were injected subcutaneously with 8 m.l.d. of the toxin alone. A portion of the toxin-emulsion mixture was next centrifugalized at 2,500 revolutions per minute for two hours, when the constituent parts of the emulsion separated into two layers. Two further groups of guinea-pigs were now injected with the aqueous layer and the oily layer respectively. The results were very clearly cut. All the guinea-pigs which had been injected with the toxin-emulsion mixture survived, whereas all the controls died within three days. The group which had received the aqueous layer after centrifugalization of the toxin-emulsion mixture also died within three days, showing a mortality rate of 100 per cent., while those in the group which had been injected with the oily layer all survived.

It is apparent from these results that when the emulsion breaks down the toxin has a greater solubility or affinity for water than for oil, even when both have been previously

mixed so as to form a very finely divided emulsion. Little or nothing has been done to determine the partition coefficients of toxins in oil and water, but it would appear from these experiments that diphtheria toxin is insoluble, or only very slightly soluble, in olive oil. This experiment was repeated using a 50 per cent. emulsion of olive oil containing gum acacia, but the emulsion was found to be so stable that centrifuging it for two hours at 2,500 revolutions per minute failed to cause anything but a very slight separation of the constituents. All the groups of guinea-pigs survived except the control animals, which were injected with toxin alone. The difference between this result and that of the previous experiment is well marked, and is probably due to the greater stability of the toxin-emulsion mixture containing gum acacia, so that the "layers" obtained from it were in reality emulsions.

EXPERIMENTS WITH LIQUID PARAFFIN

A long series of experiments, using liquid paraffin instead of olive oil, was conducted. This oil was chosen so that a comparison might be made between oils of vegetable and mineral origin. It might be mentioned here that some difficulty was experienced in preparing simple emulsions with liquid paraffin. The oil persistently separated out after standing from ten to fifteen minutes, unless an emulsifying agent such as gum acacia was added. The results obtained using this oil show that when gum acacia is added the emulsion is able to confer upon the animals a protection against the lethal effects of large doses (12 m.l.d.) of the toxins of *B. diphtheriae*, *B. tetani*, *Cl. welchii*, and *Cl. oedematis maligni* (Koch). Emulsions of liquid paraffin without the addition of an emulsifying agent are too unstable, and easily separate out into their constituent parts. The protection conferred by such emulsions was found to be of a very low order and very erratic.

CREAM OF COW'S MILK

A few experiments were conducted using this form of natural animal fat instead of vegetable or mineral oils. Milk cream is easy to obtain, and is liquid at ordinary temperatures. In the earlier experiments the toxin was added to the cream and mixed thoroughly by shaking immediately prior to injection. The results showed that this fat, when used in such a manner, afforded no protection whatever against these toxins, even when only 1.5 m.l.d. were used. In later experiments the cream was passed through a mechanical emulsifier before the addition of the toxin. The results obtained using this fat emulsion were very erratic, and very similar to those already described for liquid paraffin without the addition of an emulsifying agent.

PATHOLOGY

The pathological changes in the heart in toxæmia were studied during the course of this investigation. Necropsies were carried out on all the animals which had died from the lethal effects of the toxins used. In addition, a large number of the animals which had been injected with the toxin-emulsion mixtures, and had survived the lethal effects of the toxin, were killed and examined at varying periods, from four months to two years after the experiments. The hearts were removed within a few hours of death, and portions fixed in (a) osmic acid, (b) 10 per cent. formal saline, and (c) Carnoy's solution. Sections from the two latter were stained with haematoxylin and eosin, and haematoxylin and van Gieson's stain. In many cases the liver, kidneys, and other organs were also examined microscopically.

The effects of diphtheria toxin on the heart have led to no detailed agreement among workers, though all are agreed that the heart can be profoundly affected. Several hundreds of sections were examined by me to determine if differences existed between the tissues of the control

animals and those which had been injected with the toxin mixed with the oil emulsions.

The results show quite definitely the following features:

When death occurred in an animal which had been injected with a diphtheria toxin-emulsion mixture the post-mortem findings were almost identical with those of the control animals which had lived for a similar length of time after having been injected with the toxin alone. These findings were very constant. A large number of animals were killed and examined four months after the injection of the toxin-emulsion mixtures.

In all cases the myocardium was practically free from degeneration or fibrosis, and only very minor degrees of fatty changes were seen in a few animals. Speaking generally, the hearts showed no difference from normal healthy hearts. Another series of animals which was alive and well twenty-four months after the administration of the toxin-emulsion mixture was killed and examined. The results are in complete agreement with those just described as occurring in animals after four months.

No cardiac lesions were found in any of the animals which had succumbed to the lethal effects of the toxins of *B. tetani*, *Cl. welchii*, or the *Cl. oedematis maligni* (Koch) which could definitely be attributed to these toxins.

DISCUSSION

It is well known that fine suspensions of charcoal or kaolin have the property of adsorbing ferments and certain toxins both inside the body and *in vitro*. Finely divided oil globules in emulsions carry a negative charge, and may adsorb toxins in the same way as these colloidal suspensions. The amount of toxin adsorbed depends upon the surface area of the particles. This is dependent upon the degree of fineness of the particles in suspension, or, in the case of emulsions, upon the fineness of the oil globules. That the adsorption phenomenon of these emulsions is of the reversible type is shown by the experiments which demonstrated the recovery of the toxin in the aqueous layer after centrifugalization of the toxin-emulsion mixtures.

The pathological findings in this investigation offer strong evidence in favour of the suggestion that either the toxins are first adsorbed by the oil particles, and very slowly absorbed from the tissues, and later destroyed in the body, or that the toxins are destroyed by the emulsions. The experimental evidence outlined here would seem to favour the first suggestion. Further experiments are at present in progress with a view to determining whether an active immunity can be produced in animals in response to the injection of these toxins mixed with oil emulsions, and whether the serum of such animals is able to confer a passive immunity upon other animals against the specific toxin used. A few preliminary experiments on these lines have just been completed and appear to be very promising.

Walsh and Frazer¹² have, quite independently and unknown to me, been investigating a somewhat similar problem, and some of their results are in agreement with those outlined in this communication.

CONCLUSIONS

1. Finely divided emulsions of olive oil, when mixed with superlethal doses of diphtheria toxin and injected subcutaneously, protect animals from the lethal effects of the toxin.
2. Olive oil emulsions also protect against the lethal effects of large doses of the toxins of *B. tetani*, *Cl. welchii*, and the *Cl. oedematis maligni* (Koch).
3. The addition of a suitable emulsifying agent to give the emulsion greater stability makes the protection against the toxins secure.

4. Emulsions of liquid paraffin with a suitable emulsifying agent behave in a similar manner, but the cream of cow's milk affords no protection.

5. Coarse emulsions of these oils do not exhibit this protective action.

6. The toxins used in this investigation are more soluble in water than in oils.

7. Solutions of gum acacia do not influence the lethal effects of these toxins.

8. Diphtheria toxin, when mixed with stable, finely divided emulsions of olive oil before being injected subcutaneously into animals does not produce the myocardial degeneration which is a constant feature of the control animals.

This investigation was commenced in September, 1929, at the Pharmacological Laboratory, Cambridge, and my sincerest thanks are due to the late Professor W. E. Dixon for his interest and encouragement, and to Dr. Clifford Hoyle for his valuable suggestions and criticisms at the outset. I am also indebted to Mr. E. Saville Peck of Cambridge for his generous assistance in the preparation of the emulsions.

This communication is only an abstract of the results of this investigation, and a more detailed account will appear at an early date in the *Journal of Hygiene*.

Clinical Memoranda

A CONCEALED INCISION FOR INTERVAL APPENDICECTOMY

There is a certain class of abdominal case in which it is important to avoid anything that might contribute to the production of surgical neurasthenia. The sight of a long scar may constantly remind the patient of her operation. She begins to feel symptoms, her friends make suggestions, and sooner or later a diagnosis of "adhesions" or other trouble is arrived at. In some cases the patient becomes an invalid, and may suffer for years as the result of a simple laparotomy. Quite apart from general considerations, it is an accepted surgical principle that in operating the surgeon should aim at restoring the part to its original anatomical condi-

tion. If the scar can be completely hidden, this ideal is achieved.

Last year I was asked to perform an interval appendicectomy in the case of a nervous, highly strung young woman of 19. It occurred to me that a modification of Pfannenstiel's median inferior incision might be employed. Since then I have used this incision in about a dozen cases with entire success.

A curved skin incision is made round the mons veneris, with its convexity upwards, so that the upper edge of the pubic hair will cover the scar later. The incision is deepened through the fat, until the linea alba and rectus sheaths are exposed on either side. After undercutting, the upper flap can be pulled up sufficiently to allow of a 4 to 5 inch vertical incision through the right rectus sheath. The muscle is displaced outwards, and the peritoneal incision can then be made of sufficient length to allow of the introduction of the half hand. I have not yet found any difficulty in bringing the caecum and appendix out of the wound. The pelvic organs can be examined with great ease.

The photograph shows the incision a week after operation. More room can be obtained, if required, by prolonging the ends of the incision along the folds of the groin. A second photograph (not shown), taken from the same patient three months later, shows the line of incision completely covered.

The concealed incision is not a suitable one for every case. Suspected adhesions or the presence of any acute or subacute inflammatory condition are definite contraindications. The operation does not take any longer than removal of the appendix by the ordinary routes, and the patient has less pain and discomfort afterwards. The patient can be moved out of bed on the third or fourth day, without any risk of damage to the wound.

ERNEST COWELL, M.D., F.R.C.S.

Senior Surgeon, Croydon General Hospital.

MESENTERIC CYST

The first case of mesenteric cyst, in over twenty-five years of practice, to come under my notice is perhaps deserving of mention.

On Christmas morning, 1933, I was called to see Mr. S., aged 27 years. He stated that he had been leading an athletic healthy life. Three weeks previously he had received a severe blow in the abdomen. For a day or two following he experienced some soreness in the region of the navel. About 7.30 p.m. on Christmas Eve, following a fast sprint of one hundred yards, severe pain was suddenly felt in the region of the umbilicus. The pain, which continued all night, was somewhat relieved by the patient adopting a squatting posture.

I first saw him at 11 a.m. on December 25th. He was "doubled up" in agonizing pain. Palpation of the abdomen revealed a swelling in the region of the umbilicus. The tumour was movable in a plane from the right hypochondrium to the left iliac fossa.

No definite diagnosis was made. The physical signs indicated the presence of a mesenteric cyst. Immediate operation was advised, and the patient removed to a private hospital. An adequate abdominal incision was made over the region of the tumour. When the peritoneal cavity was opened a considerable quantity of milky fluid escaped. The abdominal swelling, now exposed, was obviously a mesenteric cyst. It was about as large as a cricket ball. A haemorrhagic area, involving the mesentery, was noted on the anterior surface of the cyst. It is probable this was caused by the blow three weeks before. The mesentery was incised and the cyst enucleated. The abdomen was closed without drainage. The patient made an uneventful recovery.

Reviews

A WEST COUNTRY PHYSICIAN'S DIARY, 1684-1726

Diaries written without a view to publication are always of interest, partly on account of the intimate details recorded which shed a light on the writer's character, and partly because they often give small facts about the life of the people amongst whom he lived. The diary of Dr. Claver Morris¹ fulfils both these conditions. He graduated from New Inn Hall, Oxford, as B.A. in 1679 and took his M.D. in July, 1691. He went out as a "grand compounder," so he must have had money. In 1683 he was admitted an extra-licentiate of the College of Physicians. It is probable, therefore, that he intended at first to practise in London. He changed his mind for some reason, went to Salisbury, and afterwards settled at Wells, where he spent the remainder of his life. Here he acquired a country practice, became a Commissioner of Sewers, had much to do in connexion with the Land Enclosure Act, and was evidently a highly respected citizen. The entries in the diary show, however, that there was something of Mr. Hyde in this example of Dr. Jekyll—not much, but just enough to prove that he was not perfect. Here is an entry: "I upped to let Coggin of Somerton in about 4 a clock with one anchor of Brandy which I bought of him. He brought also 3 Anchors more and left them in my inner cellar." It is not a solitary instance, unfortunately. Smuggling was rife, but he was never caught. Marriage was a simple matter of arrangement, and Dr. Morris acted on several occasions as a go-between. He was himself three times married, on each occasion with an eye to the main chance, and he too employed a go-between. Violent quarrels were frequent, and even the bishop could become furiously angry and express himself in no measured terms, just as two hundred years earlier the Pope used to speak to Benvenuto Cellini. Journeys were slow and hazardous; Dr. Morris preferred to make them in his calash rather than riding, as was the custom, even though the horses were sometimes so "bemired" that a yoke of oxen had to be borrowed to drag them out of the ruts. The visits were always made with a certain amount of state. A brother physician called in consultation arrived in a hired chaise drawn by six horses. Morris acted throughout his life as a consulting physician. He advised and wrote prescriptions, but they were made up for him by the apothecary, though he himself had a sound knowledge of drugs and dabbled in chemical experiments. When an operation was necessary he supervised the surgeon.

The real value of the diary lies in the account it gives of a very dark period in the history of English medicine. What were the lives and what was the social position of highly qualified consulting physicians who chose to practise in remote country districts during the seventeenth and eighteenth centuries? We know that their fellows in London secured a very high place in literary and artistic circles, but of their country cousins we know hardly anything. Apart from medicine Morris's chief interest lay in music. He played many instruments, from the organ to the flute. He was the central figure in a "Club" which undertook classical music and gave public concerts with an attendance of about thirty-two, who paid 2s. apiece when the women did not cheat.

The diary was edited by the late Dr. EDMUND HOBHOUSE, who has written a pleasant introduction. His interest in Claver Morris had already been shown by his paper on Dr. Morris's library, which was published in

the *Transactions of the Bibliographical Society* (vol. xiii, 1932-3, pp. 89-96). (The reference to it on page 8 of the foreword is incorrect.) "New Hall" on page 11 should be New Inn Hall. "Vocation" on page 122 should be "vocalion," and it is clear on page 129 that grains and not ounces are meant. Dr. Morris would certainly not have proposed to give six or seven ounces of calomel to a baby 11 months old. The book is illustrated with facsimiles of two pages of the diary, and there are some valuable extracts from his account books.

D'A. P.

BENIGN TUMOURS IN THE THIRD VENTRICLE

The removal of tumours from the third ventricle of the brain is among the most recent developments of surgery. Situated as it is in the centre of the skull the third ventricle lies at a considerable depth from the surface, and can only be explored by making wide incisions into the brain tissue. Dr. WALTER DANDY'S² record of twenty-one operations on tumours in the third ventricle is therefore a record of pioneer work, and, considering the difficulties encountered, one of remarkable achievement. His greatest success has been with colloid cysts, of which post-mortem specimens have been described at intervals during the past twenty years, but none has been successfully removed during life. Dr. Dandy has operated on five such cases, removing the cyst wall completely in all, with only one fatality. In this case blockage of the iter of Sylvius led to recurrence of hydrocephalus and death a month after operation. In tumours of other kinds, most of which arose from the ependyma and choroid plexus, the author's results have been less brilliant, as his mortality in sixteen such tumours has been 37.5 per cent., but in his later operations Dr. Dandy has reduced this percentage considerably.

These results depend as much on exact diagnosis as on operative technique. Tumours in this situation produce no localizing signs, but cause hydrocephalus by blocking the foramina of Monro or the iter of Sylvius. The ordinary methods of clinical examination will therefore give little help in localizing the tumour. Radiograms may occasionally show an opacity in the region of the third ventricle, but it may not be easy to distinguish this from the normal pineal shadow. The only certain method of localizing the tumour is, according to Dandy, total or subtotal filling of the lateral ventricles with air. This in his hands has been a safe, and even a remedial, operation. Although tumours in the anterior part of the third ventricle usually block both foramina of Monro, the resulting hydrocephalus may lead to fenestration of the septum pellucidum, allowing air to pass from one lateral ventricle to the other. Often, however, it is necessary to fill each ventricle separately. Encephalography by the spinal injection of air Dandy considers to be both useless and dangerous in cases of this kind. His operative approach to the tumours has been either by a parietal bone-flap, with retraction of one hemisphere laterally and incision of the corpus callosum, or by a frontal bone-flap, opening into the lateral ventricle through a large window in the frontal lobe. It is remarkable that neither of these incisions through cerebral tissue appears to cause any permanent loss of function. Dandy, however, carefully avoids injury to the inner part of the left frontal lobe, where he considers that the seat of consciousness lies in right-handed individuals.

It is unfortunate that this interesting monograph should be marred by innumerable misprints, which in some instances are actually misleading. Surely these are not so unavoidable as American publishers appear to consider.

HYGIENE IN OUTLINE

The term "synopsis," as applied to a work on hygiene, is so well authorized by precedent as almost to disarm criticism. Furthermore, it suggests a modesty of purpose which is itself disarming. The declared aim is to furnish an outline without filling in all details of the picture. If the canvas is stigmatized as bare the author may claim that the outlines are visible: if it is deemed overcrowded with detail he has the ready defence of the "lavish hand" and the "generous giver." Dr. CARYL THOMAS, in his recently issued *Synopsis of Hygiene*,² has on the whole maintained the strait path between shortage and excess with commendable consistency. The work, which closely follows the lines of his previous book on public health, is written throughout in a compressed style which in certain chapters reaches severity. For this, however, he compensates by most readable sections on the growth of preventive medicine, outline of English local government, history of isolation and disinfection, and other topics. The author states in his preface that his book is intended for the final-year medical student, in order to give him an outline of the various health activities of local authorities, and to assist him to realize the part taken by the general practitioner in the medical services of the country. He considers it suited to form a basis also for the work of the student preparing for advanced examinations. Owing to its synoptic arrangement it is not, we think, adapted for initial study as a textbook by either of these. To the medical student, however, as the date of his examination approaches, it will convey a salutary, if slightly depressing, admonition of the wide scope of present-day hygiene. By the student reading for a diploma in public health it will be found an invaluable reminder of points on which he would do well to refresh his memory before encountering his examiners.

THE MANAGEMENT OF CHILDREN

Many books have recently been written, and doubtless many more are even now in contemplation or in preparation, which are intended to help towards the understanding, the management, the up-bringing, and the education of young children. The two works now under review may be taken as illustrations of the two main types of such books, and may perhaps be regarded as the extremes of their types. The one, by Dr. SUSAN ISAACS, entitled *Social Development in Young Children*⁴ is a serious study of the subject—long, laborious, based upon detailed, patient, first-hand observation, and the result of extensive expert experience which deserves every respect and must be given its full weight. The other, by Dr. G. FRANCIS SMITH, entitled *If I Have Children*,⁵ is of a much more popular character, and is intended for the general enlightenment of parents, especially of young mothers.

The labours and publications of Dr. Susan Isaacs in this field of study are well known. Her present volume is the second of three works dealing in an interrelated fashion with the behaviour of young children. The first dealt with intellectual growth in young children; the second has to do mainly with their social and sexual development; and the third, still to come, is to concern itself with individual histories. Of this second volume the author says in her opening paragraph: "This book is addressed to the scientific public, and in particular to

serious students of psychology and education. It is not intended as a popular exposition whether of the psychological facts or of the relevant educational theory." The main part of the material quoted and discussed was gathered in her school for young children. The bulk of it is drawn from the behaviour of children under 6 or 7 years of age, although it contains a certain amount from those ages. The author regards it "in the first instance as a contribution to psychology rather than to education." The two major problems with which it is concerned are "the broad relation between the sexual and social aspects of development," and "the relation between the processes of education and of psycho-analysis." As will be expected by those who have some knowledge of the work and former publications of Dr. Susan Isaacs, the pure Freudian doctrine is assumed throughout to be unquestionable, and it is upon this basis that her interpretation of psychological data is given. There is no hint that the psycho-analysis of young children may be of doubtful wisdom or validity, or even that any alternative explanations of the facts adduced by such psycho-analysis are admissible. To those who are instructed and devoted disciples of the great psychologist the results and conclusions of the author will be convincing, and criticism from anyone who has not himself been psycho-analysed will be regarded as negligible and irrelevant. To other readers who are not so firm in the faith, or who are willing to accept other psychological explanations, the abundant, well-observed facts will be of great interest, but to them alternative interpretations of these facts will appear not only obviously possible, but preferable. Yet the author says, "Although my mode of presentation may at times have seemed very positive, I would not have readers assume that the views I offer are put forward dogmatically." They are intended to open up inquiry, not to close it." Further, she is careful to draw the distinction between the educator and the psycho-analyst—indeed, to emphasize the incompatibility of their functions—and fortunately we can have perfectly sound educational methods without being necessarily bound by uniform psychological theories.

The much smaller and very different book of Dr. Francis Smith is likewise founded upon experience—that of a medical practitioner of long standing. It displays, on some aspects of the subject with which it deals, a good deal of wisdom of a common-sense character, but does not reveal any close acquaintance with recent psychology, present-day human genetics, or modern educational methods and arrangements.

SURGICAL PATHOLOGY OF THE BREAST

HERTZLER'S *Surgical Pathology of the Mammary Gland*,⁶ the fifth of the series of monographs on surgical pathology in course of publication by the author, is one of the best of the series so far issued. Like its predecessors, it deals with the subject from a very practical standpoint, and is original in that it is entirely the outcome of the author's own experience. Dr. Hertzler has been in a position, in a non-urban population, to follow up the after-histories of his patients with considerable completeness, and he has found, in common with some other surgeons, that the results from operations are not as good as is generally supposed: a large number of recurrences take place after three or even ten years. At present, statistics for cancer of the gland seem, in his opinion, to be stabilizing at about 10 per cent. of permanent cures and about 20 per cent. living a substantial number of years before they succumb to metastases. A new feature in works dealing

² *A Synopsis of Hygiene*. By E. W. Caryl Thomas, M.D., B.Sc., D.P.H. Bristol: John Wright and Sons, Ltd.; London: Simpkin Marshall, Ltd. 1934. (Pp. vi + 283, 10s. 6d. net.)

⁴ *Social Development in Young Children: A Study of Beginnings*. By Susan Isaacs, M.A., D.Sc. London: George Routledge and Sons, Ltd. 1933. (Pp. xii + 480, 15s. net.)

⁵ *If I Have Children*. By G. Francis Smith, M.R.C.S., L.R.C.P. London: H. Milford, Oxford University Press. 1933. (Pp. 133, 8s. net.)

⁶ *Surgical Pathology of the Mammary Gland*. By A. E. Hertzler, M.D., in collaboration with I. A. Koenke, M.D., M.Sc. London: J. B. Lippincott Company. 1933. (Pp. xviii + 283; 240 figures, 21s. net.)

with the breast is the discussion of the social aspects of the mammary gland. In this the author has had the collaboration of Dr. IRENE KOENEKE, who is able to regard the matter from the woman's point of view. The reason for introducing this subject is the conviction that there exists on the part of many operators a lack of appreciation of the relation of the mammary gland of a woman to the fundamental factors of her life. The policy implied in such expressions as "Better remove a hundred innocent breasts than overlook one malignant" is still favoured in some quarters; women would probably apply for treatment earlier if such sentiments were replaced by a sense of obligation to furnish a correct diagnosis and the assurance of minimal therapeutic measures.

The problem of the significance of an increase in the interstitial tissue in the breast is discussed at length with the aid of a large number of very instructive photographs of the microscopical and macroscopical conditions met with. The author considers that modern views on the nature and genesis of the fibrous tissue are in so confused a state that it would be well to disregard the entire literature and build anew, but he has presented the facts very fully, so far as they are at present known, on which a final decision must rest. The subject lends itself to lengthy discussion, but, briefly, it may be said that periodical transitory variations in the amount, staining properties, and fluid content of the fibrous tissue are normal occurrences; should they produce unpleasant symptoms, however, or persist, or occur in a manifestly exaggerated degree, they have to be regarded as pathological. They are not inflammatory, although they may have a close resemblance to genuine primary chronic interstitial mastitis, except that a lymphocytic exudate is absent. Of equal interest are the author's chapters on parenchymatous hyperplasia and cysts of the breast. Special mention should be made of the numerous fine illustrations to the volume, and more particularly the large number of photographs of macroscopical sections of breasts, which are most instructive.

Notes on Books

Lymphatics, Lymph, and Tissue Fluid, by C. K. DRINKER and MADELEINE E. FIELD, is a short book describing the anatomy and physiology of the mammalian lymphatic system. It consists very largely of original observations, and is written in a most readable style. It contains a good bibliography and index.

La Digitale, by Professor HENRIJEAN and Dr. R. WAUCOMOT of Liège, is a short textbook dealing with the chemistry, pharmacology, and therapeutic use of digitalis. The authors have worked together on this difficult subject for twenty years, and their book is of interest because it presents the Continental outlook on the problem, an outlook which differs in many respects from that usually adopted in this country and in America.

The little book entitled "A Practical Work on the Most Important Infectious Diseases," by Professor C. HEGLER, director of St. George's Hospital at Hamburg, and co-editor of the second edition of Jochmann's "Handbook on Infectious Diseases," is a concise, clear, and up-to-date exposition based on thirty years' personal experience, partly in Hamburg and partly in the Balkan and World War, especially in the Sinai Desert, Palestine, Syria, and Mesopotamia, where he came in contact with some of the rarer diseases. After the war he had ample opportunity to study epidemic encephalitis, spirochaetosis icterohaemorrhagica, undulant fever, and psittacosis at Hamburg, as well as variations in the ordinary causes

of such familiar diseases as influenza, diphtheria, and scarlet fever. A short bibliography of exclusively German works is appended.

The interesting little monograph on *Chinese Medicine*,¹⁰ by WILLIAM R. MORSE, dean of the Medical School of the West China Union University at Chengtu, forms the latest contribution to the series of primers on the history of medicine known as "Clio Medica." The work is divided into twelve chapters, devoted respectively to Chinese national philosophy and cosmogony; Chinese gods of medicine; Chinese medical literature; anatomy, physiology, diagnosis, the pulse, materia medica and therapeutics, which are described as a potpourri of facts, fancies, and fatalisms; Chinese practitioners of medicine, who form a motley group of physicians, leeches, empirics, and impostors; surgery; acupuncture, which is regarded as a panacea; and conclusions. According to Dr. Morse, Chinese medicine began about 3,000 years B.C., and evolved to a relatively high standard for the age up to A.D. 1,000, since when there have been no advances to correspond with the progress of medicine in Western nations. Chinese medicine, therefore, at the present time is only of historical or philosophical interest. A valuable bibliography is appended.

The third edition of the *Scottish Youth Hostels Handbook* represents a great advance on its predecessors, both as regards the information it supplies about the progress of the parent association and the many more excellent topographical notes, illustrations, and maps. Thus in the three years it is shown that the membership has grown from just over 1,000 in 1931 to 7,082 in 1933, the number of hostels from nine to thirty-five, the beds from 227 to 1,053, and the "bed-nights" from 3,120 to 54,687. Here is sufficient indication that a real need is being met, and that the simple and health-giving life of the open air is being adopted in increasing measure by the urbanized population. No fewer than seventeen new hostels were opened during the year, and extensions and improvements effected at many of the older ones. The first town hostel in Great Britain was opened in Edinburgh last June, and was visited in four months by 1,505 persons, more than half of whom were English and 25 per cent. Scots. It is noteworthy that membership of this association carries the obligation to leave no litter anywhere, to respect private rights and natural scenery, and to avoid making any unnecessary noise. The community as a whole will benefit by extension of a membership of this kind, and the *Handbook* should provide effectual propaganda, for its contents reveal the many pleasures which are available. The description of the Border hostels indicates that it is now possible to walk from Newcastle to Edinburgh, and from Edinburgh to the English Lakes, using hostels all the way. There are rings of hostels in the Loch Lomond-Trossachs area, Perthshire, the Glen Cova and Cairngorm Chain, and the North-West Highlands. Hints are given on arranging a cycle tour in Skye, and many a rambling holiday elsewhere.

¹⁰ *Chinese Medicine*. By William R. Morse, M.D., LL.D., F.A.C.S. New York. Paul B. Hoeber. 1934. (Pp. xxiii + 185; 16 figures. 2.50 dollars.)

New Preparations

DRY LIVER EXTRACT

Hepamult (H. R. Napp, Ltd., 3, Clements Inn, W.C.2) is a dry extract of calf's liver. The activity of the product is controlled by clinical tests which show that 10 grams of Hepamult have a haematopoietic equivalent to 8 ounces of fresh liver. The usual daily dose is 10 to 20 grams. The extract is said to be prepared by a novel and economic process, which enables it to be marketed at an extremely cheap rate. The price to the medical profession is 20s. for 16 ounces, and this works out at about 5d. per dose of 10 grams. The makers point out that therapy with this extract is actually cheaper than when fresh liver is used. The quantitative estimation of the activity of liver preparations is a matter of exceptional difficulty. If, however, the makers' estimates of activity are correct, Hepamult will represent an important therapeutic advance, because the cost of liver extracts hitherto has been a factor seriously limiting their employment.

THE ILL EFFECTS OF RADIATIONS

Dr. Hector Colwell and Professor Sidney Russ, both with long radiological experience, as shown by an earlier collaboration on radium, α rays, and the living cell, have appropriately dedicated their authoritative work, *X-Ray and Radium Injuries: Prevention and Treatment*,¹ to Dr. Stanley Melville, who, although he died before the volume was published, knew of this well-deserved tribute. Melville had done a great and lasting service to his colleagues in all countries by initiating in 1921 the first X-Ray and Radium Protection Committee, which standardized recommendations forming the basis for those adopted internationally at the Stockholm congress in 1928. Professor Russ and he had been the honorary secretaries of this committee since the start. It is interesting to learn that Professor von Roentgen escaped any untoward effects because, in order to avoid fogging of unexposed plates in the neighbourhood of Crookes's tubes, he had performed most of his experiments, which were mainly photographic, with the tubes inside a large zinc box protected, in addition, by lead screens. An early pioneer, Dr. F. H. Williams of the Boston City Hospital, being convinced that with such penetrating power α rays must exert some effect on human tissues, by his foresight in adopting protective measures did not have the terrible experience of so many early radiologists, especially the pain of α -ray carcinoma so graphically described by the late Dr. Hall Edwards in the *British Medical Journal* thirty years ago. The authors show that there have been roughly two hundred fatal cases of α -ray carcinoma, which on an average occurs at about the age of 40, much earlier than ordinary skin cancer, some nine years after the first exposure, and nearly always on the back of the hands. A number of cases have followed α -ray treatment of lupus, and, as this sequence is well known to occur without radiation, the authors insist that lupus should not be treated by α rays until all other means have been exhausted.

Some modern authorities throw doubt on the factor of idiosyncrasy in the occurrence of α -ray and radium injuries, and, indeed, seem to regard this as a euphemism for faulty technique. Dr. Colwell and Professor Russ do not discuss this attitude, but describe as the four causes of casualties: errors in dosage; idiosyncrasy; an unrecognized focus, such as a pyosalpinx which may flare up when a carcinoma of the cervix is being treated by irradiation; and the difficulty in

getting radium needles into exactly the right position and keeping them there. The whole subject is considered systematically under the headings of the skin, the respiratory, circulatory, alimentary, generative, urinary, nervous, and other organs, and full reference is made to the work of others. It is pointed out that in the early stages of radio-dermatitis itching rather than pain, which is correlated with ulceration later, is often most distressing.

Whereas the cutaneous lesions caused by α rays and radium soon became unpleasantly obvious, there was a long delay before the blood changes were recognized; attention, indeed, was first drawn to this subject in 1904 by Heineke, who investigated the cause of death in irradiated animals without any skin changes, and pointed out the leucopenia. The question whether leukaemia in an α -ray worker, a rare event, is a coincidence or a result is discussed by Dr. Colwell and Professor Russ, who reach the cautious conclusion that for the present the positive association cannot be dismissed. It is impossible to deal with all the important material so admirably marshalled in this monograph, but we feel confident that it will long remain a source of reference on the injuries due to irradiation, which, with adoption of the means of protection here advocated, should in the future have mainly an historical interest.

CANCER AND CHEMICAL STIMULI

Those familiar with modern developments in cancer research often feel moved to correct popular ideas about "the cause of cancer" and the alleged fruitlessness of experimental studies. The position is that many undoubted causes of cancer are known, at least in the sense of agents which constantly produce the disease. What we do not know is whether there is some unknown underlying mechanism common to the action of all of them, or whether cancer from the aetiological point of view is not one disease, but several. It is difficult to believe that a malignant teratoma appearing early in life has anything in common, as concerns its origin, with epithelioma of the tongue complicating syphilitic leucoplakia: one appears perfectly to exemplify the origin in "embryonic rests" postulated by Cohnheim; the other, to illustrate malignancy induced by a specific type of long-continued irritation. It may be said that there are four fully ascertained causes of experimental cancer, not without their parallels in the human disease (the word "cause" being used in the sense already defined): hereditary susceptibility, which can be increased by inbreeding until the occurrence of a particular type of malignant disease is almost constant; parasitic infestation—*Spiroptera neoplastica*, for example, constantly giving rise to a carcinoma of the stomach in rats; chemical and physical irritants, such as tar, oils, excessive exposure to light, and even α rays and radium—agents

¹ *X-Ray and Radium Injuries: Prevention and Treatment*. By Hector A. Colwell, M.B., Ph.D., M.R.C.P., and Sidney Russ, C.B.E., D.Sc. Oxford Medical Publications, London, Humphrey Milford, Oxford University Press, 1934. (14s. net.)

which from industrial and clinical experience were evidently carcinogenic and have all been shown to be so by animal experiment; finally, the virus or whatever type of agent may be held responsible for the filterable tumours of birds. A unifying conception which will explain the origins of all these forms of malignant disease in the same terms cannot even be formulated. The two last in particular would seem to be fundamentally different in nature: the recent claim of McIntosh¹ to have transmitted a chemically induced growth in the fowl by means of a cell-free filtrate affords what appears to be a connecting link between them, but raises difficulties which are still far from elucidation.

Perhaps the nearest approach towards such a unifying conception as we have envisaged, though it is still highly speculative and the limits of its application cannot be defined, is that which has arisen from the study of carcinogenic hydrocarbon compounds. The discovery of these substances by Professor E. L. Kennaway and his co-workers² was in itself a landmark in the progress of this branch of cancer research, since until then the composition of the active agents in carcinogenic tars had not been ascertained. It was known only that treatment by a certain degree of heat, the optimum lying at about 850° C., whether of coal or of certain other materials, led to their formation. The key to the recent discovery of their nature was the observation that the fluorescence spectrum given by carcinogenic substances prepared in this way corresponded closely to that of compounds of the dibenzanthracene series. These could be synthesized, and several synthetically prepared agents of this nature were found to be actively carcinogenic. For the induction of tumours by means of tars of complex composition it has hence been possible to substitute the use of single reagents of exactly known chemical composition. The first suggestion that these discoveries led any further than relating carcinogenic activity to chemical structure came in the astonishing observation made by Cook and Dodds³ that two of the most active of these carcinogenic hydrocarbons are also oestrogenic. To this, from the experimental standpoint, there is nothing yet to add; but speculation has a solid basis in the fact that there is a close relation in chemical constitution between the carcinogenic hydrocarbons, and substances, including oestrin and cholesterol, which are present normally in the body. The direction in which speculation is proceeding is naturally this: Is the immediate stimulus to malignant proliferation the presence of a compound of the nature of those we have been considering which has actually been formed in the body? Such an assumption as this might be capable of explaining the action of a great diversity of agents in producing cancer: it might well, for example, account for the effect of such physical stimuli as ultra-violet light, heat, and x rays.

Whether, or no further development of this study yields confirmation of this hypothesis, it is clear that the fully ascertained facts as they stand are of profound and fundamental consequence; they surely afford a sufficient answer to those who accuse experimental cancer research of leading nowhere. Since the whole of this work has been carried out in England, it is of interest to observe the reaction to it in other countries. Sannie and Truhaut,⁴ representing the French point of view, conclude a general review of the subject of chemical carcinogenesis with a detailed appreciation of the work of Professor Kennaway and his colleagues, in which they acclaim it with enthusiasm. An American journal has furnished hospitality to the extraordinary observations of Burrows and N. M. Kennaway,⁵ which must also be mentioned in this connexion. In view of the observation by Cook and Dodds, to which reference has already been made, it was clearly necessary to ascertain whether oestrin itself could excite malignant proliferation. This apparently it does not, but repeated application to the skin is followed not only by a series of changes of considerable interest in the reproductive organs of either sex, often eventually fatal owing to urinary obstruction, but in males by the development of massive scrotal hernias which may come to contain a large proportion of the abdominal contents. This quite unexpected consequence so far lacks any explanation.

THE BED-BUG ON THE MAP

The central departments of health have certainly "put the bed-bug on the map." In August, 1933, the Department of Health for Scotland issued a treatise on the bed-bug written by Dr. William Gunn of the Public Health Department of Glasgow. Reference was made to this booklet in the *British Medical Journal* of November 11th, 1933 (p. 885). The Ministry of Health for England has similarly been studying this pest, and an important report on the eradication of bed-bugs, prepared by a committee of experts under the chairmanship of Dr. G. W. Monier-Williams, was submitted to the Minister of Health at the end of last year. This report⁶ has now been circulated to local authorities by the Ministry of Health, together with a memorandum⁷ on the bed-bug and how to deal with it. Although there is no evidence that the bed-bug conveys disease to human beings as fleas carry plague, lice typhus fever, or mosquitos malaria, it is nevertheless a pest from which many householders in poorer localities suffer. It may be that bed-bugs are responsible for actual ill-health from lack of sleep due to skin irritation. It has even been suggested that it is possible to pick out from groups of school children those that come from bug-infested houses by reason of their sallow complexions and listless appearance, but this is obviously little more than theory.

¹ *Bull. de l'Assoc. Française pour l'Etude du Cancer*, 1934, xxiii, 6.

² *Amer. Journ. Cancer*, 1934, xx, 48.

³ *Reports on Public Health and Medical Subjects*, No. 72. Ministry of Health: Report on the Bed-bug. London: H.M. Stationery Office, 1934. (1s. net.)

⁴ *Memo. 180, Med. On the Bed-bug and How to Deal with It.* H.M. Stationery Office, 1934. (3d. net.)

⁵ *Brit. Journ. Exper. Path.*, 1933, xiv, 422.

⁶ *Proc. Roy. Soc. B*, 1932, cxi, 455.

⁷ *Nature*, 1933, cxaxi, 203.

Of the two documents now issued for the use of sanitary authorities the memorandum is much the more important for practical purposes. It states briefly and clearly the life-history of the bed-bug, tells of the indications of the presence of bed-bugs, and suggests where bed-bugs should be looked for when a dwelling is being inspected. This information is likely to prove extremely useful to the sanitary officer in connexion with both housing conditions and the management of housing estates owned by local authorities. The memorandum goes on to give the sources of infestation and the methods for prevention of infestation and for extermination. With regard to this last matter—namely, prevention—neither the report nor the memorandum adds much to what has already been so well said by Dr. Gunn in the treatise to which reference has already been made. The important point is that after all it is the housewife who must clean her house with care and regularity. There is no agent more effective in ridding a house of bed-bugs than the diligent application of soap and water, to which a little washing soda has been added. A disinfectant such as cyllin may be used with perhaps some advantage, but not in place of soap and water. Help should be given to tenants so that they may know the harbourages of bed-bugs—for example, behind pictures and picture rails, architraves, skirting boards, window mouldings, in cracks in plasterwork, in old articles of furniture, behind loose paper on walls, and where the upholstery meets the actual woodwork of furniture. Bugs are also found on bed mattresses and bedding, especially around the leather button of the mattress. All these special sites should be known to the sanitary officer, who should assist the tenant with his advice on how to get rid of them. Various contact insecticides are mentioned by the expert committee, but it is frankly stated that the relative effectiveness of these insecticides cannot yet be assessed from a practical point of view. With regard to fumigation, all that is known is that prussic acid gas, in a concentration of about 2 per cent. by volume with an exposure of three hours, will usually penetrate all ordinary types of hiding-place and kill bed-bugs and their eggs. Fumigation by this gas may be carried out in the homes, or the furniture may be similarly fumigated in specially devised vans. In both cases, however, there are grave dangers, and the use of prussic acid gas, except under the close direction and supervision of specially trained workers, should not be undertaken. Special measures, too, require to be adopted to free articles of furniture and particularly bedding of this poisonous gas after fumigation.

The memorandum also deals with the removal of tenants to new premises, and emphasizes that before the move takes place a thorough and not a cursory inspection of the old house and furniture should be made. Infested furniture should on no account be removed to the new house, and if such furniture cannot be destroyed its thorough disinfection must be accomplished before it is used in the new home. The memorandum winds up on the keynote which is dominant throughout—namely, that to prevent infestation or re-infestation the inculcation of habits of cleanliness among the tenants should be the primary object of the sanitary officer and property manager.

CARBON TETRACHLORIDE POISONING

Advances in industrial chemistry have led to the introduction into the domestic and the commercial worlds of a wide variety of organic chemicals, and some such innovations have not been free from dangers to health. Carbon tetrachloride is a case in point. As a liquid it is a non-inflammable fat solvent. It forms a heavy and non-inflammable gas, and hence is a valuable fire extinguisher; it is also employed very extensively as an anthelmintic for hookworm. The use of carbon tetrachloride for dry shampooing quickly provided proof of its toxic properties, for in England a case of poisoning occurred in 1907 and a death in 1909. This fatality led to the abandonment of carbon tetrachloride for shampooing in this country; but a recent report¹ contains an account of a case of poisoning from this cause in Denmark as lately as 1932. Such a risk can, however, be easily avoided, for there are alternative and safer solvents for dry shampooing, and hence carbon tetrachloride should not be allowed for this purpose. As an anthelmintic it has produced a large number of fatalities, but unfortunately there is no efficient cure for hookworm that is absolutely safe. The relative merits of remedies for ankylostomiasis are a matter of dispute. Carbon tetrachloride has become the drug of choice in many countries, but some authorities state that it should not be prescribed on account of its toxicity. For example, Clayton Lane² speaks of its administration in the treatment of hookworm infestation as "a blindfold gamble with death," and considers "the use of the drug inadmissible in the present dosage even for the individually attended patient." Incidentally, the medicinal employment of carbon tetrachloride has added much to our knowledge about its poisonous actions. Specimens contaminated with carbon bisulphide are extremely toxic, but even in the purest form it can give rise to toxic effects. Experiments on dogs have shown that it can readily produce liver degeneration, but that a considerable degree of protection can be afforded to the liver by an adequate supply of calcium. The industrial dangers of carbon tetrachloride have been recently reviewed by Möller.³ In particular he discusses the use of this drug for industrial and domestic dry cleaning, in connexion with which a number of cases of poisoning have been reported. On the other hand, it is non-inflammable, and the number of deaths from burning due to benzene must be far greater than the fatalities for which carbon tetrachloride is responsible. Möller concludes that carbon tetrachloride is, on balance, probably safer than benzene, provided that the public are instructed that it forms a heavy and toxic gas, and that great care in ventilation must be taken after it has been used. As a fire extinguisher it has been found invaluable in electric plants on account of its non-conductivity, and, in the case of petrol fires, because its heavy fumes blanket the fire. But even when employed for this purpose it is not without its dangers, and three cases of poisoning have been recently reported by Sir William Willcox,⁴ and another one in Paris.⁴ In these instances the outstanding feature was

¹ *Journ. Indust. Hygiene*, 1933, xv, 418.

² *Hookworm Infection*, Oxford University Press, 1932, p. 229.

³ *British Medical Journal*, January 20th, 1934, p. 105.

⁴ Gautier, Chatron, and Seidmann: *Bull. et Mém. Soc. Méd. des Hôp. de Paris*, 1933, No. 34, 1838.

impairment of kidney function. Möller points out an additional risk attending the use of carbon tetrachloride in fires—namely, the possibility of partial oxidation of the drug, with the formation of phosgene. Petrol fires are so dangerous and they are so difficult to put out that it is scarcely justifiable to condemn an efficient extinguisher because of its toxic properties. Every effort should be made, however, to educate the public to the risks associated with carbon tetrachloride. The peculiar danger is that the heaviness of the fumes, which makes the compound such a good fire extinguisher, also makes the fumes difficult to remove, and very thorough ventilation is necessary before it is safe to enter a room in which carbon tetrachloride has been liberated in quantity.

EXPERIMENTAL CORNEAL GRAFTING

The work of Mr. Tudor Thomas in corneal grafting is well known. His latest contribution¹ deals with improvements in the technique of experimental grafting in rabbits, an investigation into the causes of opacification in grafts, and a new method of examination of the anterior chamber in cases with general corneal opacities precluding direct observation. It seems quite clear that at present heterogeneous grafts cannot be successfully used, since an opacity which never clears always forms in the alien tissue. This is very unfortunate, as it is a matter of practical experience that, human donors being all too few, a careful selection of recipients has to be made, and borderline cases, where the results are uncertain, have to be denied the possibility of improved vision. An adhesion of the iris to the back of the graft results in formation of an opacity, and, by eliminating the danger of anterior synechiae in experimental animals, the solution of the similar problem in human eyes is one step nearer. Details of the best form of corneal needle to give accurate suturing and to avoid perforation of the anterior chamber, together with the easiest way of threading eyeless needles, have now been satisfactorily worked out. The new method of examination of the position and size of the pupil and the depth of the anterior chamber, where the cornea is opaque, by simultaneous and successive transillumination of the globe from two directions, greatly assists in the prognosis and selection of cases. It enables the operator so to place his graft that it lies over the pupil in a position of maximum efficiency. Previously in a very opaque cornea it was sometimes discovered towards the end of the operation that the graft would be eccentric to the pupil, and that a portion of the graft would be useless unless an iridectomy were performed later. This method of examination can also be used to determine the effect of mydriatics and miotics on the pupil. It has the added advantage of being easily applied to a patient on the operating table. The operation at present can hardly be performed with success by anyone who has not had practice on animals, but, by continued experiment, the ingenuity of Mr. Tudor Thomas will be able so to simplify the technique that a more universal practice of grafting will be possible. Mr. Thomas's paper allows a glimpse of the great amount of investigation and experimentation that has led, during some

years past, to the evolution of the operation. It is estimated that in animals useful vision is obtained in 75 per cent. of cases. No figures of the results obtained in man are given, but, even if they fall far short of this high percentage, the operation, which had in the past been abandoned as useless, marks a notable achievement in ophthalmic surgery.

SIX DUBLIN DOCTORS

As a result of the cholera epidemics which worked such havoc in Ireland the hospital of Saint Vincent de Paul was opened in Dublin in 1834. In the recent "Record of the St. Vincent's Hospital Centenary," Mr. William Doolin, surgeon to the hospital and editor of the *Irish Journal of Medical Science*, has given, under the title of "The Forerunners," sketches, remarkable for their interest, of the early members of the staff. The first, and for some time the only, medical officer was a surgeon, Joseph Michael O'Ferrall (?1790-1868), who spelt his name at different times in other ways—Farrell and Ferrill—and is said to have preferred it to be pronounced "O-ver-all" as an expression of universal superiority. He was poor and of humble origin, raised by his own exertions, a stern, thrifty, and egotistic character, who wrote 109 papers; as his sight failed he successfully cultivated the *tactus cruditus*, and when from paraplegia he had to be wheeled into the wards still continued his clinical teaching. As the hospital grew it became necessary that he should have a colleague, and this again was a surgeon, O'Bryen Bellingham (1805-57), and it would be difficult to find a greater contrast than that between these two. Bellingham came of an ancient family dating from the Conquest, and taking its name from Bellingham-in-Tyndale in Northumberland; a Sir Edward Bellingham was Lord Deputy of Ireland in 1548, and O'Bryen was born at Castlebellingham, County Louth, as the son of Sir Alan Bellingham. He took the degree of M.D. at Edinburgh, and with his social advantages rapidly gained practice in Dublin, was a member of "Our Club," or "The Rough and Readys," was a gentle aristocrat, courteous to all, professor of botany and librarian at the College of Surgeons, famous for his method of curing aneurysm by manual compression, and the exhibitor of so many specimens of this lesion before the Pathological Society that it came to be known, among the physicians, as "The Aneurysmal Society." He wrote an excellent work on *Diseases of the Heart*, which contained a very good account of exophthalmic goitre, but he did not live to read the laudatory notices it evoked. Edward Mapother (1835-1908), the only one of the six included in the *Dictionary of National Biography*, taught Alexander Macalister and many others their anatomy, held the chairs of hygiene and of anatomy and physiology, was the first medical officer of health for Dublin, and president of the Statistical Society, evidence of rare versatility, before he removed to London and became a dermatologist. The fourth appointment to St. Vincent's Hospital was that of Robert Cryan, a wealthy and shy personality, and the first "pure physician" in Dublin; another physician, also well endowed with this world's goods, was T. B. Quinlan; a hospitable, scholarly man, of sunny disposition,

¹ Brit. Journ. Ophthalm., March, 1934, p. 129

popular as an examiner, and more sympathetic than many of his colleagues with the candidates. The last of the "Forerunners," William O'Leary, was a surgeon of rare promise, "lost in politics," who became a member of Parliament, and died when little more than 40.

CARE OF MENTALLY AFFLICTED IN LONDON

The discharge of the duties of the London County Council in regard to the mentally afflicted forms the sixth volume, just issued, of the Council's annual report for 1932.¹ How large a population of mentally disordered or mentally deficient persons London has to carry may be judged from two figures. The number of persons for whose accommodation under the Lunacy and Mental Treatment Acts the Council was responsible at the beginning of last year was 21,760. The total number of defectives who had been ascertained at that date as subject to be dealt with, or as those who might become subject to be dealt with, was 15,890. In other words, one person out of 200 in the population of London is an inmate of a mental hospital, and one person out of 274 is a mental defective. The number of mental patients in London county hospitals is rising very slightly. It has been within one thousand of what it now is for the last five years, and even as far back as 1910 it was within 1,800 of the present figure; during the war years, however, there was a decrease of over 1,000 a year. The number of patients discharged as "recovered" since 1895, when the records were first kept, is shown to be 38,194, but 12,126 of these were readmitted to a London mental hospital, 4,202 of them within twelve months of their discharge. At the date of the present report there were 749 alien patients in the London county mental hospitals, of whom more than one-third were of Russian nationality. Another interesting fact to be gleaned from the many tables appearing in the report is with regard to the work of the psychiatric out-patient clinics which were established in May, 1931, under the provisions of the Mental Treatment Act, at three of the general hospitals under the management of the Public Health Committee of the Council. The number of such patients treated during the year under review was 963; of these, 737 were disposed of, so far at any rate as out-patient treatment is concerned, before the year ended, sixty-four were admitted to the wards of Maudsley Hospital, and 162 were still attending at the end of the year. The new cases under the Mental Deficiency Acts with which the Council was called upon to deal during the year numbered 1,719, and it is noteworthy, when so much is said about the criminal tendencies of the mentally defective, that only fifty-nine of these were criminal cases. Of these new cases 1,072 belong to the category of feeble-minded, 531 were imbeciles, and 115 were idiots; one was a moral defective. It is reported that the ascertainment of these cases indicates the further progress made in the exhaustive ascertainment of London cases of mental defect previously in Poor Law care. As already stated, the total number ascertained is 15,890, or 3.65 per 1,000 of the population of the county of London, but the real number of defectives is much

larger, because many cases, chiefly defectives who left the Council's special schools some years ago, have been known to the Council for the last nineteen years, though, for various reasons, they are no longer on the Council's books, even for friendly visitation. One curious point is the undue proportion of defectives in North-East London. During the last three years the proportion of defectives dealt with in North-East London has been 37.3, 35.5, and 31.2 per cent. respectively, as compared with 12.5, 15.3, and 13.4 respectively in the South-West. The disparity is, no doubt, open to a simple explanation, but it illustrates the fallacy of taking a local section of a community and presuming that the results apply in the larger area.

THE PASTEUR INSTITUTE, PARIS

On May 17th the ten members of the executive committee of the Pasteur Institute met and elected by a unanimous vote Dr. Louis Martin as director of the Institute in succession to Roux, and Dr. Gaston Ramon as subdirector in succession to Calmette. The importance attached to these appointments in France was emphasized at the election by the presence of a former President of the Republic, Raymond Poincaré. A "conseil scientifique" has been created with the object of providing an advisory body destined to strengthen the hands of the new chiefs of the Institute in the framing and executing of scientific policies. The members of this new body include Bordet of Brussels, Gabriel Bertrand, A. Borrel, Mesnil, Nicolle, and Yersin. Dr. Martin, who has been subdirector of the Pasteur Institute since 1917, was born in France in 1864, and Dr. Ramon, who was born in France in 1886, has for long been, and still is, director of an annexe to the Institute in Garches, one of the suburbs of Paris.

RESEARCH DEFENCE SOCIETY

At the annual general meeting of the Research Defence Society, to be held at the London School of Hygiene and Tropical Medicine, Keppel Street, W.C., on Tuesday, June 5th, at 3 p.m., the chair will be taken by the president, Lord Lamington, supported by Sir Arthur Stanley and Professor A. V. Hill, F.R.S., chairman and vice-chairman respectively of committee. The eighth Stephen Paget Memorial Lecture will be delivered by Professor Joseph Barcroft, F.R.S., on "Experiments on Man." Tea and coffee will be served after the meeting.

We have to announce with much regret the death of Mr. Andrew Fullerton, C.B., C.M.G., lately professor of surgery in Queen's University, Belfast. Professor Fullerton had been President of the Royal College of Surgeons in Ireland, of the Association of Surgeons of Great Britain and Ireland, and of the Ulster Branch of the British Medical Association.

We regret to announce also the death of Dr. David Ogilvy, medical superintendent of the London County Council Mental Hospital at Long Grove, Epsom. A memoir will appear next week.

¹ Annual Report of the London County Council. Vol. vi. P. S. King and Son, Ltd., Westminster. (1s.)

CLEAN WOUNDS, ANCIENT AND MODERN

PROFESSOR GASK'S ORATION

The Annual Oration before the Medical Society of London was delivered on May 14th by Professor George E. Gask, whose subject was "Clean Wounds, Ancient and Modern." It had been intended that Sir Charles Sherrington should be the Orator, but he was prevented by illness from fulfilling his promise.

THE MODERN SURGICAL OUTLOOK IN ANCIENT
EGYPT

Professor GASK began by saying that there had been at least two periods in past ages during which the treatment of wounds had been rational and cleanly. One of these was in ancient Egypt, during the time of the building of the Pyramids. About that time there lived a surgeon who wrote the earliest book extant on surgery, or, indeed, on any branch of medicine. So early was it that many of the most common anatomical terms had not been invented. The author had no word, for example, for the convolutions of the brain, and so he likened them to the coils which molten copper made when poured into a mould. But he knew a great deal about anatomy and surgery; he was aware, for example, of the right way to treat a fracture of the upper end of the humerus, that the arm should be abducted, and he came very near to discovering the circulation of the blood. His book was written on a papyrus roll, the beginning and end of which was missing, and so the name of the writer was not known: The papyrus was found about 1860 by an American Egyptologist, Edwin Smith, who took it to America, where it remained untranslated, and at the finder's death was presented to the New York Historical Society, and eventually translated by James Henry Breasted and given to the world in 1930. The book was written as a form of instruction to students, and forty-eight cases were described, with a detailed account of the wound or injury, the diagnosis, prognosis, and treatment.

Four points emerged from the method of treating wounds so described. The wound was to be treated with fresh meat, which was to be bound upon it for one day. Stitching was to be done at once. If the stitching was loose it was to be drawn together by two strips. After the end of the first day the wound was to be treated with grease and honey until it recovered. The use of fresh meat seemed rather a barbarous method, but one remembered that the application of raw beefsteak to a black eye had been a favourite treatment among pugilists for hundreds of years. Again, many a surgeon, bothered at operation by a bleeding point, snipped a piece of muscle and put it over the point, like a postage stamp. Was there possibly some bactericidal principle in fresh meat? Professor Gask said that he had asked Dr. Lawrence Garrod at his hospital to carry out some experiments. He got meat which had been recently killed, and, shredding it, put it in test tubes with some sterile water, and added certain micro-organisms. He found a slight diminution in the tubes containing streptococci and *B. pyocyaneus*, and his conclusion was that raw meat might assist bactericidal action, but for a short period only. The weak point in the experiment was the impossibility of obtaining meat directly it had been killed—the interval was eighteen hours. Altogether he thought that the modern surgeon should raise his hat to the ancient Egyptians. They had at least a cleanly and rational method of treatment, infinitely superior to the methods which were in vogue in a later age.

LIGHT IN DARK AGES

The Orator then spoke in passing of the wisdom and sanity of the Hippocratic school in ancient Greece, but as Greece declined, medicine and learning generally shifted towards Alexandria and Italy, and the Romans borrowed their art, science, and medicine from the Greeks, and in his opinion did not improve it particularly. The great Galen, who worked in Rome about A.D. 180, favoured dogma rather than the old method of observation and deduction. Superstitions of all sorts were entertained, one of the worst being the idea that suppuration was necessary for the healing of a wound. This must have caused an infinite amount of suffering, and one wondered what heights surgery might have reached in those centuries if only the cleanly methods of the Egyptians and the Greeks had persisted.

After the fall of Rome and the plunging of Europe into darkness, the scene reopened at Salerno, the first medical school in modern history. In 1180 Roger wrote his *Practica Chirurgicae*, but he followed the Galenic doctrine and promoted suppuration. But there arose at that time the dim figure of Hugh of Lucca, who left no writings, and what was known of him was through his disciples—some said his son—Theodoric, who wrote a book on surgery in 1266. It was evident that neither the master nor his disciple believed that suppuration was necessary to the healing of wounds, and they made a daring break-away from the tradition and authority which was then paramount and ruling the schools. Afterwards there came Henri de Mondeville, born in Normandy soon after it was lost to the English crown, a daring and original man, who, in 1301, was one of the surgeons of the King of France. He also wrote a book on surgery, and one's admiration for him was all the greater when it was realized that at that time ignorance and superstition were paramount, and authority was quoted as gospel. Henri derided the treatment of wounds by the method of the ancients, as he called it, and, considering that he knew nothing about micro-organisms, it was astonishing what a forward-looking mind he displayed, though he himself said it was dangerous for a surgeon to operate otherwise than was the custom of other surgeons. He illustrated in his method the essentials of modern aseptic treatment, and no dead hand of classical medicine was upon him.

THE LISTERIAN ERA

Professor Gask finally took his audience in imagination to the town of Lille in the middle of the nineteenth century, where, in a small and rather badly furnished chemical laboratory, Pasteur made the illuminating discovery that fermentation and putrefaction were due to living micro-organisms. Pasteur lit a candle which illuminated the whole world; but it was not of Pasteur he wished to speak, but of one phase of Lister. No praise was too great to give Lister. Had he lived in the time of the ancient Egyptians he would have been deified like Imhotep, but his country did its best by sending him to the House of Lords! It seemed almost an act of impiety to question at all Lister's method of thinking and working, yet the Orator had often wondered why Lister chose such an inconvenient method of antiseptics as carbolic when he had the agent heat at hand. Many surgeons could remember the discomfort of having to sterilize their hands in 1 in 20 carbolic, how cracked and sore and bleeding they became, and the relief when heat was substituted for the chemical. Why did Lister adopt carbolic? Lister went to Glasgow in 1860, when he was distressed at the ravages of hospital gangrene. A colleague at Glasgow at that time was Thomas Anderson, regius professor of chemistry, a very intelligent and

travelled man, who had studied under Berzelius in Stockholm and under Liebig in Germany. Professor Gask believed that it was Anderson who told Lister of Pasteur's discovery. In a letter he had received from Dr. Freeland Fergus, a Glasgow student who knew Lister, it was stated that there was no doubt that the first time Lister heard of Pasteur's work was during a walk with Anderson. Lister and Anderson lived near each other in the west of Glasgow; the university was in the east, and it was possible that they often walked together. One could imagine Lister impressed by the discovery that the micro-organisms were the cause of putrefaction, and asking whether it was possible that they were the cause also of suppurative and of hospital gangrene, and what methods he should adopt to kill them. There were three methods available—filtration, heat, chemical disinfectant; and Lister chose the last, probably because Anderson, his adviser and friend, was a chemist, and therefore would be likely to think along chemical lines. It was probable also that Anderson told him of the circumstances that at Stannix, a northern suburb of Carlisle, where a sewage farm had been established, and where there was great outcry owing to the smells, experiments had been carried out to get rid of the smell by using crude carbolic acid. Lister used carbolic acid, and the rest of the story was known to the world.

It would be interesting to speculate what would have happened had Pasteur been the surgeon instead of Lister. He believed that he would have chosen heat as his disinfectant rather than chemicals, for in 1874, when Pasteur addressed a gathering of surgeons, he urged that surgical instruments should be put through a flame, and he also said that were he a surgeon, not only would he use absolutely clean instruments, but he would make use of bandages and sponges which had previously been raised to a considerable heat.

Clifford Allbutt used to tell of an old country veterinary surgeon a hundred years ago who had wonderfully successful cures, but he guarded his secret jealously. On his death-bed, with his dying breath, he whispered to his son, "I hiles my tools."

Neither Pasteur nor Lister had an altogether happy old age. Metchnikoff, in his posthumous work *Trois Fondateurs de la Médecine Moderne*, said of Pasteur that his old age was not happy. In spite of the adoration of his family and the devotion all around him, he fretted himself constantly because his work was unfinished. Lister, too, Professor Gask had been told, was not entirely happy as an old man. He did not see the need for modern operating theatres. The ritual of cleanliness in those theatres he regarded as unnecessary, and he thought the lessons he had taught had been wasted.

"I think it is right," said Professor Gask in conclusion, "that we should pause a minute to take a legitimate pride in these discoveries and the world-wide application which has made modern surgery what it is. Like the mountaineer, we may pause awhile and look back into the mists of the valley out of which we have struggled, and pay our tribute to the good men who have led us. But now that our guides have dropped back into the shadows we have to turn our faces to the steep ascent, because the mountain top lies still far above us. But it is cheering to know that our young men are now, better than ever before, full of enterprise and energy, and they have a task before them which is worthy of them."

Sir D'ARCY POWER proposed a vote of thanks to Professor Gask, which was seconded by Sir CHARLES BALLANCE. The latter said that he thought he knew why his great teacher, Lord Lister, adopted carbolic. He (Sir Charles) entered St. Thomas's at a time when very few operation wounds in the London hospitals healed by first

intention: At St. Thomas's at that time, in what was known as No. 8 block, all the cases which suppurated and got septicaemia and other diseases were transferred from the wards. The operating theatre was dirty, the assistants at the operations were dirty, the surgeon was dirty, the patient was dirty, everything—the whole environment—was filthy, and he believed that was one of the reasons why his great teacher chose carbolic acid, and in his first case, a compound fracture of the leg, he used this crude carbolic, and the patient's wound healed, without fever and without pain.

England and Wales

Prevention of Tuberculosis

The twentieth annual conference of the National Association for the Prevention of Tuberculosis, which will take place in London on June 14th and 15th, will be conducted in the form of an all-round discussion on twenty-one years' experience of the National Tuberculosis Scheme. The time seems ripe for a review of the progress made towards the original objectives and of knowledge gained in various fields, when it is recalled that the national campaign was inaugurated by the report of the Departmental Committee on Tuberculosis in 1912-13. The conference will be held at the County Hall, and its first meeting will open with a welcome extended to it by Lord Snell, chairman of the L.C.C. The conference will then be opened formally by the Minister of Health, after which Viscount Astor, who was chairman of the Departmental Committee on Tuberculosis, will deliver an address. He will be followed by Drs. Salisbury MacNalty and Noel Bardswell and Sir John Robertson. These proceedings will occupy the morning of Thursday, June 14th. In the afternoon the main discussion will be continued, special attention being given to the tuberculosis dispensary. The opening speakers will be Dr. Lissant Cox and Dr. Melville Dunlop. Residential institutions will be considered on the following morning, the first speakers being Drs. James Watt, R. C. Wingfield, J. B. McDougall, and F. R. G. Heaf. The discussion will be continued in the afternoon by Dr. H. P. Newsholme and Miss Edith McGaw. The conference is open to all persons interested in tuberculosis on payment of one guinea, either as delegates or as private members. This fee includes the supply of a copy of the report of the proceedings. Members of the association, and one member each appointed by societies affiliated to it, are entitled to attend without payment of the fee. The Minister of Health has now reverted to the former practice of sanctioning the payment of the reasonable expenses incurred in connexion with the attendance of two delegates from county councils or boroughs, of whom one should be either the medical officer of health or the chief clinical tuberculosis officer, or of three delegates when it is considered desirable that both should attend. Individual applications to him for sanction within this limit are no longer necessary.

The St. Mary's Hospitals, Manchester

The report of the maternity department of St. Mary's Hospitals, Manchester, for 1932 has now been issued, and contains the usual classified statistics and clinical details. During that year 3,604 maternity patients were treated by the hospital staff—2,401 in the wards, and 1,203 in their own homes. Of the thirty-three deaths nine were in booked cases and twenty-four in emergency cases, representing mortality rates of 1.37 per cent. for the total—0.62 for the booked cases, 0.69 for the total booked deliveries, and 2.61 of the total emergencies.

There were 204 cases of puerperal morbidity (measured by the B.M.A. standard), a percentage rate of 9.74. Of these cases 119 were booked and eighty-five were admitted as emergencies. In the 262 cases of abortion there were three maternal deaths, due respectively, to septicaemia, diabetes, and cardiac insufficiency—in all instances following therapeutic abortion by Taylor's bag. In the wards were treated 347 cases of contracted pelvis, of which 247 were booked, the maternal mortality percentage rates being 1.6 in emergency cases and the same in booked cases. The foetal mortality percentage figure was 7.7 per cent. There were seven cases of ectopic pregnancy, in one of which rupture had occurred. All were treated by abdominal section, and the patients recovered. Of twenty-two eclamptic patients admitted as emergencies four died, a mortality rate of 18.2 per cent. In each instance death ensued some time after recovery from the eclamptic state, the cause being pulmonary embolism in two, melancholia in one, and pneumonia and empyema in the fourth. The method of treatment has been, since 1928, a combination of the Dublin and Stroganoff lines, a procedure modified since January, 1930, by the addition of intravenous glucose and intramuscular magnesium sulphate injections. Half an hour after the injection of morphine sulphate, coramine, magnesium sulphate, and dextrose, gastric lavage is employed, there being left in the stomach 2 ounces of castor oil and 2 minims of croton oil. Colonic lavage is also performed, under anaesthesia if necessary, 2 ounces of magnesium sulphate being left in the colon. An hour later 30 grains of chloral hydrate are given by the mouth or rectum, subsequently succeeded by morphine sulphate and coramine at intervals. The patient is nursed in a darkened ward, and precautions are taken to ensure absolute quiet. Strict attention is paid to keeping the air passages clear, and oxygen is used if there is cyanosis. The report concludes with short notes on the fatal cases.

The Health of Newcastle's Children

An investigation into the health and nutrition of preschool children in Newcastle-on-Tyne has recently been carried out by Dr. J. C. Spence.¹ Representative sample groups of children were selected from maternity and child welfare clinics, the Salvation Army Sunday School, and the casualty department of a dispensary. The parents were unemployed in a large proportion of cases. For comparison 124 children of better-class families living under good conditions were also investigated. A thorough clinical examination was carried out, and the age, weights, and heights were recorded. A number of x-ray examinations were made to estimate the incidence of rickets, and haemoglobin estimations were carried out to study anaemia. Rather more than half the children were found to be below normal weight and rather less than half below normal height. Only five out of 103 children examined for rickets showed any active disease, but 23 per cent. were anaemic. Assessment of the physical condition from general appearance, stature, and weight revealed that 32.8 per cent. were satisfactory, 20 per cent. unsatisfactory, and the rest average or moderate. Dr. Spence was not, however, satisfied with this rather superficial examination, and when the results of the blood and x-ray examinations were correlated he had to remove five anaemic children from the satisfactory group and three rickety children and twelve anaemic children from the average group. The results indicate that out of 125 children of the city forty-five were found to be unhealthy (36 per cent.) Of these, twenty seemed to owe their ill-health to some preceding illness such as

measles, bronchopneumonia, or sepsis in skin, glands, or ear. In the history of the remaining twenty-five there seemed to be no cause other than malnutrition. An inquiry into housing showed that children could be brought up healthy in bad housing conditions, but that there was a direct relation between overcrowding and ill-health. The average of the whole group was 2.6 persons per room. The medical officer of health of the city, in a note appended to the report, deplors the absence of toddlers from child welfare centres; and points out that the population of the city at this period of life may fail to come under medical supervision. The case mortality rate for measles, he observes, is three times greater in overcrowded areas than in residential districts, and he regards premature attacks of infectious disease as the heritage of the slum child. From an analysis of family budgets in fifteen houses it appears that the amount spent weekly on food during January and February of this year was 4s. 5.8d. A diet based on the Ministry of Health standard would have cost 5s. 1½d. at the current prices. He therefore recommends the improvement of much of the existing housing accommodation, provision of more hospital accommodation for measles, whooping-cough, and convalescence, an extension of the milk issue to children between 1 and 4 years of age, and the education of mothers in the compilation of diets.

Social Hygiene Summer School

The annual summer school of the British Social Hygiene Council will be held at Digswell Park Conference House, Welwyn Garden City, from June 25th to 30th, in conjunction with the vacation school for colonial administrators and missionaries, the programme being specially designed to present the scientific background of social hygiene as a coherent whole. Professor Raymond Firth will deliver a course of five lectures on anthropology, Mr. D. Ward Cutler a course on biology, and Professor A. E. Heath a course on psychology. The inaugural session will be addressed by Professor F. A. E. Crew. This study of fundamental principles will be related to the problems of daily life at home and abroad by means of seminars each afternoon. For the home group the discussions will be centred round the problems relating to family stability and preparation for marriage. Enrolment forms are obtainable from the secretary of the council, Cartaret House, Cartaret Street, S.W.1. The membership fee is £1 1s., and the boarding fee £2 7s. The annual report of the council for the year ending May 31st, 1933, gives an account of the propaganda conducted throughout the country, and related work in the Dominions and foreign countries. The more medical side of the work was extended, and closer co-operation has been attained with public health authorities. The biological side of the educational activities has also increased considerably, and the various cinematographic films have been in great request. Among the subjects to which special attention was devoted during the year under review were the promoting of regular attendance for treatment of congenitally syphilitic children, the instructing of pupil midwives in venereal diseases, the treatment of women in rural areas, and sterilization in mental diseases.

Diet for Spa Patients

The important question of diet for patients undergoing spa treatment has lately been the subject of conferences between the Spa Subcommittee of the Bath Division of the British Medical Association, the Spa Committee of the Bath Corporation, and the Bath Hotels Association. By the co-operation of all these bodies a scheme has been evolved and recently put into operation whereby visitors requiring special diet will receive a diet card from their physician which they will hand to the

¹ Investigation into the Health and Nutrition of Certain of the Children of Newcastle-upon-Tyne between the Ages of One and Five Years. By J. C. Spence, M.D., F.R.C.P. Newcastle-upon-Tyne: Co-operative Printing Society Ltd.

head waiter or manager of their hotel, who will then see that the doctor's instructions are carried out. Unless some specially expensive article of food is ordered, no additional charge will be made to dieted visitors. The diet charts contain a very full list of articles of food and drink, but before being handed to the patient the doctor will delete all dishes to be avoided. Thus the individual treatment of every patient, to which the Bath Medical Committee attaches so much importance, will be provided. Small cards, informing visitors of the scheme, will be placed on all hotel tables. British spas have been much criticized, especially recently, for their alleged neglect, as compared with Continental resorts, of cure diet, and it is hoped that the scheme Bath has evolved will do much towards meeting this criticism. At the same time, it avoids either unnecessary restrictions, which are often of no real value to the patient, or routine methods imposed regardless of the peculiar conditions of the individual case.

Scotland

Work of a Tuberculosis Colony

The report for 1933 by Dr. J. Johnstone, physician-superintendent of Hairmyres Colony, Lanarkshire, deals with the question of tuberculosis in children. The after-health of two groups of children discharged from the colony in 1923 and 1930 were followed up. It was found that of the first group 83 per cent. of the boys and 94 per cent. of the girls were in good health in 1933, while in the second group 67 per cent. of the boys and 71 per cent. of the girls had recovered and maintained good health. During the past year a change had been made in the type of case admitted to the colony, which now receives patients in all stages of tuberculosis, although a certain number of beds are still reserved for those who are physically fit for systematic training. The number in residence at the beginning and end of the year was 227, while there had been 214 admissions and discharges in the course of the year. Of the 214 patients discharged 93 suffered from pulmonary tuberculosis and 103 from non-pulmonary tuberculosis. Of these tuberculous patients 70 per cent. had come from houses of less than three apartments. An open-air school had been one of the features of the colony, and the education of the children had been satisfactorily maintained. The training departments of the colony included gardens, a forest nursery, a poultry farm, a piggery, and workshops, and in these the patients had been trained by experienced instructors during working hours varying from two to six daily, according to the patients' condition.

Health of Dunfermline

The annual report of Dr. C. Barclay Reekie, medical officer of health for Dunfermline, shows that the number of births registered during 1933 was 678, giving, after correction, a birth rate of 15.6 per 1,000 as against 15.4 in the preceding year. The infantile mortality rate was 46 as compared with an average of 57 for the last five years; this is the lowest rate on record for the burgh. The death rate after correction was 12.8 per 1,000, which is slightly above the average of 12.54 for the last five years. The chief causes of death were heart disease, malignant tumours, apoplexy, bronchitis, pneumonia, and tuberculosis. Two reservoirs of the burgh were unable to maintain the water supply during last summer's drought, but with help from the county reservoir, which had a statutory obligation to augment the burgh supply, there was no scarcity. With regard to infectious diseases,

there were 426 notifications of scarlet fever with three deaths, fifty-eight first notifications of measles with no death as compared with 703 notifications in the previous year, fifty first notifications of whooping-cough with two deaths, and forty-five cases of diphtheria with one death. There had been nine cases of puerperal pyrexia and six of puerperal sepsis with one death, and thirty-three notifications of pulmonary and twenty-one of non-pulmonary tuberculosis. Four health visitors were employed by the burgh who visited notified cases of tuberculosis, and a dispensary was maintained at which 131 persons attended during the year; twenty-two patients were treated in sanatoria. The report draws attention to the maternity service and child welfare scheme. Health visitors made 514 first visits to infants, and 5,518 revisits, while 158 first visits were paid to expectant mothers, of whom a large number were referred to their family doctor for advice. Four child welfare clinics were maintained, where the number of attendances by children under one year was 1,661, and under 5 was 1,290. There were 443 admissions to the maternity home, an increase of eleven over the previous year; since its establishment twelve years before the total number of admissions had been 3,576. There were two maternal deaths in the year, and 344 live births. A scheme is proposed for the extension of the home at a cost of £27,000.

Home Relief for Incurables

At the annual meeting of the Royal Society for Home Relief to Incurables in Edinburgh Bailie Kinloch Anderson, who presided, said that the society had carried on useful work for 128 years, dealing with applications for assistance from all parts of Scotland. In the past year the society had distributed a sum of £5,173 among 465 beneficiaries. The total revenue of the society had amounted to £6,523, and its expenditure to £5,933. Separate from the ordinary funds was the Dunlop Cancer Fund, which was managed by this society for the relief of patients suffering from cancer, and out of this fund a sum of £1,892 had been distributed last year. Lord Murray said that anyone who read the report of this society's work must recognize that it deserved support. He had often in his professional life been engaged in winding up private firms and public companies, but he had never helped to close any charitable institution which had been doing good work. He therefore confidently appealed to those of the public who could afford it to support this society.

According to J. Godínez-Rivera (*Thèse de Paris, 1934, No. 155*) in Mexico typhus is most prevalent in the capital and the towns of the central plateau, where the disease is endemic, with occasional more or less severe epidemics during the winter. As in Europe, the cases are most frequent among the very poor. Typhus is rarely found in the low-lying regions near the coast, the virus apparently not being able to become habituated to tropical temperature. The clothes louse is not found in that country, but there is an abundance of rats and fleas, by which the disease is transmitted. The average annual mortality per 100,000 inhabitants from typhus in Mexico City in recent years has been as follows: 1898-1905, 173.5; 1906-15, 144.5; and 1916-25, 76.6. In 1932 it was only 5.2, but in 1931 it rose to 30.9, owing to an epidemic during the first few months of the year. The fall in the typhus mortality is attributed to the reorganization of the Mexican Health Service which took place in 1920. Good results have followed the prophylactic use of the Zinsser and Ruiz-Castaneda vaccine, which is prepared from the tunica vaginalis of infected rats and administered subcutaneously in increasing doses (1.2, 1, and 1½ c.cm.), with an interval of one week between the doses. The duration of the immunity so conferred has not, however, yet been determined.

Reports of Societies

SURGICAL TREATMENT OF CARCINOMA OF THE COLON

At a meeting of the Subsection of Proctology of the Royal Society of Medicine, on May 16th, with Mr. ERNEST MILES in the chair, a discussion took place on "Surgical Treatment of Carcinoma of the Colon."

Dr. FRED. W. RANKIN, late of the Mayo Clinic, and now of Lexington, Kentucky, opened the discussion, and showed a cinematograph film of his operation. He said that carcinoma of the colon must, in most instances, be considered as a problem for the surgeon. It occurred most frequently in middle-aged individuals, and these were found to benefit enormously by certain preoperative measures. Decompression in the preoperative stage was a fundamental principle. It might be accomplished in a period of from three to six days by medical measures, including mild purgations, or, these failing, by a surgical measure, either ileostomy or caecostomy, the latter being distinctly the procedure of choice. Blood transfusion had proved highly desirable. He was still somewhat uncertain about the utility of the employment, as a preoperative routine, of vaccination. He believed that it increased the individual's resistance against infection and built him up to withstand an operation of which peritonitis, either local or general, was a very usual accompaniment, but he would not abandon any of the other preliminary measures in favour of vaccination simply. Turning to operative procedures, Dr. Rankin said that the most usual technique which had been employed with advantage in the right half of the colon was aseptic ileocolostomy. He favoured in every case where it was possible an end-to-side anastomosis between the terminal ileum and the middle of the transverse colon. The end-to-side method was more advantageous than the lateral. There must be a number of times when it was permissible or even desirable to carry out a one-stage resection for right colonic cancer, and it seemed to him that the principles of the graded operation were required more pointedly in the left colon than in the right. The history of resection of the left half of the colon was marked by attempts to do single-stage operations, with a high mortality accompanying almost every such attempt. He then discussed, first of all, decompressive measures in the left colon, favouring caecostomy (of the Hendon or Gibson type), with colostomy and ileostomy as alternative procedures. The extirpative measures were: obstructive resection (after medical decompression); resection and anastomosis or obstructive resection (after surgical decompression); and exteriorization (Mikulicz) procedures. In his hands mortality from aseptic ileocolostomy had been lower than in any other type of left colon operation. The intensity of the malignant invasion was the most important single factor in prognosis. Of his 187 cases of carcinoma of the right colon 34 per cent. showed glandular involvement, and of his 266 cases of carcinoma of the left colon 31 per cent. showed such involvement. He would have supposed on theoretical grounds that the left colon would show the higher incidence of involvement, but, even so, the right colonic cancers, instead of the higher percentage of glandular involvement, showed a higher percentage of five-year cures. Of the cancers of the rectum 46 per cent. of his 300 cases showed glandular involvement. He did not know why cancer of the rectum should metastasize so much more frequently. There was no reason to believe that it lay dormant and unrecognized for a longer time than cancer higher up. He divided the cases into four grades from the point of view of glandular involvement on resection, and showed how in the right colon the percentage of five-year cures progressively diminished with the successive grades of involvement. In the first grade 63 per cent. showed a five-year cure; in the second grade the figure fell to 51 per cent., and in the third and fourth grades to 31 and 24 per cent.

respectively. The number of five-year cures was as follows:

	No. of Cases	Dead	Cures
Right colon ...	187	81	116
Left colon ...	266	139	127
Rectum ...	300	186	114
Total ...	753	406	347

Dr. Rankin then projected an admirably produced film illustrating every detail of the operation of aseptic end-to-side ileocolostomy; in particular, the use of the Rankin clamp between the lower portion of the ileum and the side of the transverse colon, and the two rows of catgut sutures employed in making the anastomosis. The film also showed the technique of resection, carried out, it a graded operation was decided upon, after an interval of two to four weeks. A right rectus incision was made, the colon being delivered out of the wound, and mobilization accomplished by dividing and resecting the colon with the cautery.

Sir CHARLES GORDON-WATSON said that there were very few surgical fields where judgement and experience played so important a part as in relation to malignant disease of the colon. One surgeon might regard a case as inoperable and suitable only for short-circuit or colostomy, whereas another, perhaps of greater experience, might realize that a wide resection after careful mobilization, and perhaps removal of a portion of the small intestine, though presenting very definite risks, offered a chance of cure and was a wise alternative to the inevitable sentence of death if a radical procedure was not carried out. Many cases which at first appeared too advanced for radical surgery could be attacked successfully after a carefully planned mobilization. It was difficult to assess the value of statistics, because the higher the operability rate for resection the higher the mortality, and vice versa. He thought that a very high operability rate for resection must be the aim, the endeavour being made at the same time to reduce the mortality rate. If one excluded a large number of cases by calling them inoperable, and was content with short-circuits and colostomies and the like, a low mortality rate could, of course, be shown for resections. His own figures showed a five-year survival rate of 33 per cent. after resections; he feared that this did not compare well with Dr. Rankin's cases. In his first series of cases, from 1921 to 1926, the operability rate was 57 per cent. and the mortality rate 20 per cent.; in his second series, from 1927 to 1932, the operability rate went up to 71 per cent. and the mortality rate down to 12 per cent. That was definite evidence that results were improved with increasing experience. At the same time other things had been improved also, including methods of anaesthesia. The enormous value of blood transfusion, both before and after radical procedures, had also to be emphasized. He thought that in radical colon surgery drainage first spelled safety. This was perhaps specially true for those who had their spurs to win in colon surgery. As experience increased, the surgeon could determine when it was justifiable to employ resection either in one or two stages without preliminary drainage, and could also determine when the risks were too great for primary procedures. It was not necessary to emphasize what was now an established surgical principle: that a primary resection was never justifiable in the presence of any form of obstruction; but he wished to point out that he considered that every case of left-sided colon growth did produce some degree of obstruction—in other words, every patient with a growth in the distal colon was potentially obstructed. The toxic state of the bowel behind the growth was a definite menace to aseptic surgery, and this was sometimes lost sight of by the unwary. In pelvic colon surgery it was very seldom possible to do a side-to-side anastomosis, and to remove sufficient bowel and mesentery there the surgeon was reduced to some form of end-to-end anastomosis. In other parts of the colon it was generally possible to do a side-to-side anastomosis, and he believed this was much safer. It was possible to get an opening which was larger

than the natural diameter of the bowel, and therefore there was far less risk of gas distension at the site of the anastomosis. With an end-to-end anastomosis he had had the experience of after-contraction, and that often led to trouble. With regard to marsupialization or exteriorization operations, he wished to make a claim for priority for Paul of Liverpool, as against Mikulicz or any of the other surgeons Dr. Rankin had mentioned. The advantages of the Paul operation were inestimable, and if there was doubt about primary resection nothing better than the Paul operation could be done. By employing a No. 10 catheter some few inches above the anastomosis the risk of gas distension for the first twenty-four hours after the operation was avoided. With regard to methods of immunization of the peritoneum, in 1911, with Dr. Gordon at St. Bartholomew's, he tried to see what could be done to immunize the peritoneum with vaccines, and he gave it up. On the whole question he was quite sure that better results could be obtained than those at present forthcoming, and he thought it possible that results would be better when more was known about the use of the diathermy knife. When the diathermy scalpel was used more frequently there would be an advance in this field of aseptic surgery. He believed also that there were possibilities in the future with regard to both radium and x rays in advanced cases. The time would come when, with the million-volt x rays or the heavy radium "bomb," it would be possible to attack these cases with short exposures combined with surgery. He hazarded the view that when the Section met in ten years' time the mortality rate for the resection of the colon would be down to about 5 per cent.

Mr. J. P. LOCKHART-MUMMERY was pleased to see that Dr. Rankin had made an important point of the decompression of the bowel before doing any radical operation. He agreed also that multiple-stage operations were of the greatest value in many of these cases. There were cases where it was advisable and perfectly feasible to do single-stage operations, but many in which such operations would be very dangerous. One point which had rather struck him was the question of shields around the point of anastomosis. After an anastomosis of the colon one was liable to have the elbow of the small gut caught up against the suture, and it had been his habit to bring down a piece of omentum and stitch around the point of anastomosis, or even to use detached grafts of omentum for that purpose, such detached grafts maintaining their vitality quite well. The most difficult cases were those of carcinoma in the lower end of the pelvic colon. Whereas the cases on the right colon did very well, and many on the left extremely well, the really unsatisfactory cases were those in which the growth was situated at the lower end of the pelvic colon and could not be mobilized so as to bring it properly outside the abdominal wall. With regard to Paul's operation, where the growth was mobilized, he thought it very important that the limbs of the colon should be stitched together so that no mesentery could get between the two ends when the clamp was used later. If the mesentery did get between the two ends it would be caught in the clamp, and trouble of some kind would ensue.

Mr. GORDON-TAYLOR praised the Paul-Mikulicz operation. Many of the colons with which he had to deal were in stout persons, where suturing was very difficult, and where the diagrams seen in the textbooks showing the accurate use of the sutures did not apply. The old Paul operation of mobilization of the bowel and bringing it up to the surface, although it was a retrograde operation, carried with it little or no mortality. He believed that he had done Paul's operation at least forty times, and in the difficult, fat patient, the case which was a bad operation risk, the operation had a distinct value. It was most important to do a caecostomy, and this was done even in the cases where he carried out a Paul-Mikulicz operation. It added another stage to the operation, but it made the prognosis even better. In the majority of cases of carcinoma of the colon, when the abdomen was opened, there was no evidence of sub-hepatic metastasis or evidence of peritoneal involvement, and provided there were no secondary manifestations of

the primary growth, and the growth could be mobilized no matter what its extent, surely it was worth while dealing with these cases radically. He had removed part of the abdominal wall with a carcinoma of the colon in at least a dozen cases, and in most of these cases the temerity and enterprise of the surgeon had been well rewarded by a long survival after the original operation.

Mr. LAWRENCE ABEL agreed with what had been said about the value of blood transfusion both before and after operation. It was a procedure which Mr. Miles and he had used for a number of years now, and they thought its use had lowered the mortality, both immediate and remote. He had learned his colon surgery from Mr. Trotter, who advised that when a growth was anastomosed it should, if possible, be extraperitonealized. That was a procedure he had carried out in only a dozen cases; in the last five of those he had used Dr. Rankin's clamp for an immediate anastomosis of the bowel, and he spoke highly of its value. He believed that extraperitonealization of the anastomosed loop was possibly some insurance against the development of peritonitis. Another thing which prevented post-operative distension was continuous intravenous salines after operation. His impression was that patients so treated had a much easier post-operative course. Mr. W. B. GAUBIEN was not quite in agreement with some of the previous speakers as to the necessity for a caecostomy. He believed that it was possible, if one did an old-fashioned Paul operation, even though there was a salubac obstruction, to do the operation with complete safety without a caecostomy. This did not apply, of course, if there was complete obstruction.

Dr. RANKIN, in reply, considered that an average operability rate of 63 per cent. as given by Sir Charles Gordon-Watson was a splendid result; it was higher than his own average for the last eight years.

PSYCHOLOGY OF THE MENOPAUSE

At a meeting of the Medical Society of Individual Psychology on May 10th, when the president of the society, Dr. ALFRED ADLER, was present, Dr. MARY BELL FERGUSON read a paper on "Neuroses of the Menopause."

Dr. Ferguson said that the subject of menstruation was important to anyone who dealt with women, whether as patients or as workers. The girl's attitude formed in adolescence would affect her throughout the whole reproductive cycle and change of life. In the past it would be fair to say that many people, including members of our own profession, had regarded the change of life as a time of sickness, which might range from minor ailments such as headaches, to grave mental illness. Until recent years little research had been made into the psychology of menstruation. In 1925 the Medical Women's Federation had instituted an inquiry into menstruation in school-girls. From the report based on this inquiry it was found that disturbance in general health and happiness was definitely related to the presence of pain. In 1926 the Federation appointed a subcommittee "for the purpose of investigating from the clinical aspect phenomena associated with the menopause." From the findings of this report it was apparent that normal menstruation tended to be followed by a normal menopause, and a history of dysmenorrhoea by more marked menopausal symptoms. Mr. Aleck Bourne, in his paper "The Chronic Pelvic Woman," had emphasized the mental and human aspects of the problem, so often overlooked by thinking in terms of viscera and not enough in terms of mind and nervous system. These aspects were more important than ever, since women were now working citizens, compelled to earn their own living. As work in many fields before the war was regarded as "men's work," and as the higher education (so-called) of women was largely on boys' lines, was it to be wondered at that women developed a "masculine protest"? Dr. Ferguson then gave details of two cases in which psychotherapy had been effective in enabling the patient to adjust herself to the change of life.

CORRESPONDENCE

The Medical Charities

A Plea for a Great Campaign

SIR,—Despite the efforts of the Central Charities Committee and of devoted workers up and down the country it must be acknowledged that there is still much ignorance regarding the medical charities, and that the funds available are insufficient to meet the clamant needs of the distressed members of the profession and their dependants. In all respects the situation is unsatisfactory, and it is time that the facts should be clearly stated and boldly faced.

1. The charities are able to deal only with the most pressing needs. Maintenance grants and annuities are pitifully meagre, and the educational opportunities of the girls are much inferior in number and value to those offered to the boys.

2. The number of those practising medicine increases steadily year by year, while economic conditions are making it more and more difficult for them to earn a livelihood, and the standard of living is tending to fall. Thus there is good reason to expect that in the future a larger number will find it impossible to make adequate provision against illness and accident and for retirement, and, in consequence, the number of those requiring charitable aid will probably be larger in future years.

3. Even should the contributions to the charities continue to grow it is very improbable that the growth will be rapid enough to suffice to meet the needs of the charities.

In short, the present methods are quite inadequate to meet present needs, and will probably remain so, at any rate for many years. Are we, then, to be content to continue as at present, or have we the courage and determination to make a supreme effort to place the finances of the charities on a sound basis? Action on a large scale is necessary—much more ambitious and far-reaching than anything previously attempted. My proposal is that a great campaign be organized, culminating in a special charities week. For this purpose a combination of forces is essential, and the help of the Royal Medical Benevolent Fund, Epsom College, the Royal Medical Benevolent Fund Guild, the Medical Women's Federation, and other representative bodies should be enlisted, and these, with the united forces of the British Medical Association, working through the Council, the Representative Body, the Divisions and Branches, and Panel Committees, should take part in this great effort.

The aims of the campaign should be: (1) to spread knowledge of, and create interest in, the medical charities; (2) to increase the number of regular subscribers to the charities; and (3) to raise a large capital sum the interest of which, after investment, would be available for special purposes—for example, the education of girls, more annuities, etc. I suggest a capital sum of at least £25,000. The methods of the campaign should include: (1) a personal canvass of every member of the profession; (2) securing the invaluable help of the wives and families of members of the profession and of other sympathizers; and (3) the use during the special week of every possible legitimate means of raising funds—for example, dances, bridge drives, concerts, sales of work, "bring and buy" sales, etc. Further, the services of the medical press should be enlisted to bring the needs of the charities before their readers and spur them on in all their efforts on behalf of this great cause.

I write this letter in the hope that this suggestion may stimulate interest and provoke discussion.—I am, etc.,

ARNOLD GREGORY,

Charities Secretary, Manchester
Division, B.M.A.

Manchester, May 14th.

Pathogenesis of Tumours

SIR,—Tumours, malignant and non-malignant alike, are composed of cells that imitate, more or less successfully, those from which they grow. There are therefore as many kinds of tumours as there are different kinds of tissues, and only a general classification is possible. There is, for example, no single form of cancer, but as many varieties, differing from each other clinically and anatomically, as there are varieties of epithelium; and the same thing is true of sarcoma and of non-malignant growths.

Tumours are not mere outgrowths from the tissues. They are more than that. They are the offspring of the tissues, with a life of their own, distinct from that of the structures from which they grow. It is true they depend upon these structures for everything that makes life possible; and that of necessity they die when their support dies; but they will continue to grow and thrive even though the parent organism starves to death. They are, in short, the offspring of the tissues, living upon them as parasites, and belong not to the same but to the next generation. Growth and reproduction are essential features of life. They are the heritage of every living cell, and if conditions are favourable they never cease to exert their driving force so long as life continues.

Every organism is composed of a number of cells which almost at once separate into two main groups: one for the preservation of the race, the other for the maintenance of the individual. The former are concerned solely with reproduction. The latter have to undertake every kind of work that is necessary for existence, and as they never have anything to do with reproduction they gradually lose the power. The tumours that grow from the former are capable of reproducing an almost perfect individual. As a rule these growths begin in the earliest moments of existence, and therefore can only be due to their innate reproductive power acting with exceptional energy. Those, on the other hand, that are developed from the maintenance group of cells present much greater variety. Just at first these cells, like the others with which they were originally equal, can throw off a bud which will grow into a more or less perfect individual; but growths of this kind are very rare in man, though they occur not unfrequently in some of the lower animals.

The vast majority of tumours spring from tissues developed out of these cells, but only from those that are not so highly specialized as to have lost the power of reproduction. Cells of the nervous system, for example, have completely lost it, and never form tumours. The cells of which these tumours are composed may attain the same standard of development as the original, but they never pass beyond it. There is never any organization, order, or arrangement. The tumours simply consist of masses of cells, all more or less of the same pattern. Development has come to an end.

The character of these tumours depends upon the stage the parent cell had reached at the moment that development was arrested. Development is the product of inheritance. Growth is part of life, controlled and guided by development. Arrest of development, leaving growth free from control, is well known in connexion with many organs of the body, and if in the case of the cells from which the tissues are derived development is stopped at the beginning while they are still in the actively growing cellular stage, there is nothing left to control growth but the supply of food.

The development of the individual is an epitome of the evolution of the race. The young cell is the victim of heredity. It is compelled by it to undertake the work of its forefathers and give up reproduction. If it were not for all that it has inherited it would be free to live on the same evolutionary level as a unicellular organism; and if it is freed from its inheritance while it is still so

young it will multiply in just the same way. If the original was still in possession of all its embryonic powers its descendants will possess them too. They will be able to move about, partly by their own power, partly carried by the lymph stream, and will spread in all directions, forming colonies wherever they settle. The result is a widely spreading tumour composed of nothing but young cells, usually of very rapid growth, carcinoma or sarcoma, according to the layer of the blastoderm from which the parent came.

If, on the other hand, before development is arrested the parent cell has become so far specialized as to have lost much of its original power of reproduction, without losing the whole, and has attained the standard of a well-formed tissue, the daughter cells will multiply more slowly and will approach the same standard, though they will never rise above it, for development is stopped. Then, instead of invading surrounding structures, they simply push them on one side, and the surrounding structures treat them as a foreign body and throw a kind of capsule around them.

Arrest of development may probably be caused by many different agencies, but there is very little definite known about them. X rays appear to have the power, for they have been shown experimentally to be able to influence the development of the embryo; and the slowness with which the injuries they sometimes inflict are repaired suggests that their action has affected the growth and development of the tissues around. There is no evidence that the numerous exceedingly diverse agencies that lead to cancer can cause actual arrest of development, but because of the length of time they all, without exception, require before there is any effect it seems probable that they are not so much the direct cause as intermediate agents that induce some necessary preliminary change in the affected tissues, perhaps in the nature of developmental arrest. Moreover, it is not unknown for the first evidence of cancer to appear some considerable time after the reputed cause has ceased to act, and it is not without significance that in many cases crops of innocent tumours, papillomata and the like, caused by the same agent, precede the outbreak of cancer by many months.—I am, etc.,

C. MANSELL MORTLIN, D.M., F.R.C.S.

Consulting Surgeon to the
London Hospital.

The Cancer Problem

SIR,—I recognize that my statement about cancer (May 5th, p. 803) should have been accompanied with particulars in justification. The question of the increase of cancer was thoroughly sifted a few years ago in Germany. The analysis showed that where an increase is observed some definite condition can generally be detected in explanation; and that if all such instances of increase are excluded from the statistics no general increase is indicated by the figures. In other words, there exists no general condition tending to increase cancer, and no general rise in susceptibility to cancer. The question of an increase of cancer, therefore, turns entirely on special cases and their valuation as significant or insignificant. Take the increase of cases of cancer of the lungs, rightly or wrongly attributed to the introduction of petrol. The following figures are from Hadfield and Garrod's *Recent Advances in Pathology*, and relate to post-mortem room statistics:

All Necropsies:

An increase in cancer from 0.51 to 2.05 per cent. between 1907 and 1925 (London Hospital); 0.24 per cent. before 1885, 2.57 per cent. between 1911 and 1925 (Manchester).

Cancer Cases Only:

An increase from 0.54 to 7.2 per cent. between 1886 and 1926 (Vienna); from 3.3 to 7.5 per cent. between 1903 and 1906 (Berlin).

Similar results are reported from St. Bartholomew's Hospital, and from Basel, Leipzig, Hamburg, Zurich, and certain Russian and American authors. I have no statistics at hand relating to the increase connected with the use of creosote, aniline, tar, mineral oil, arsenic, irradiation, and other causes depending on social conditions and habits which will readily occur to every pathologist. Whether the increase is preventable or not is beside the question. That modern civilization is developing an uncanny faculty of increasing cancer appears to me hardly to admit of doubt. Some people would extend its responsibility to the past.—I am, etc.,

May 19th.

THE REVIEWER.

Heredity and Hyperpiesia

SIR,—Dr. Herbert Brown is surely mistaken when he writes in the current number of the *Journal* that "few, if any, writers have drawn special attention to the factor of heredity" in the aetiology of hyperpiesia. I thought it was common knowledge. In a monograph on *Diseases of the Kidney* (Ball and Evans), published in 1932 (p. 266), the present-day opinion is stated as follows: "It is common to obtain a family history of cerebral haemorrhage or death from myocardial disease in those who suffer from hyperpiesia. Heredity is the one established factor in the aetiology of the disease." A typical case history is then given in illustration. When so much in regard to hyperpiesia is a matter of doubt it seems worth while emphasizing a fact about which there is no doubt.—I am, etc.,

London, N.W.1, May 21st.

GEOFFREY EVANS.

Cardiac Massage

SIR,—Surely the time has come when we should examine our consciences on the subject of cardiac massage. How often do we perform it with the real hope of restoring life—life in its true sense, not merely temporary reanimation? Again, how often do we perform it because it is expected of us? Unfortunately the subject has received unenviable publicity in the lay press, largely through the medium of the coroners' court. This in itself is significant: the cases are ultimately the subject of a coroner's inquiry.

In the some half-dozen cases which have occurred in this hospital during the last nine years I have observed a uniformity in the sequence of events. The patient collapses, and the ordinary routine of resuscitation is applied; finally, cardiac massage is attempted, the heart beat is re-established, and the patient returns to the ward, but not to consciousness. During the next twelve to twenty-four hours he passes from one clonic fit to the next, with a steadily rising temperature, and finally dies in high pyrexia. This cannot be regarded as restoration to life. The brain, and more particularly the mid-brain, does not survive the lack of its circulation for any considerable period, and yet the impression is created in some quarters that the greater the time lapse the greater the miracle of restoration. The condition of the "restored" is comparable to that of the physiologist's decerebrate frog.

It would seem that there is only hope when cardiac massage is applied immediately, and, generally speaking, this is only possible when the abdomen is already opened

for the purposes of the operation. To employ cardiac massage as a last resource is worse than useless; it is a mutilation of the deceased.—I am, etc.,

L. T. CLARKE.

Strangulated Hernia

SIR,—Mr. Huckell, in his letter to the *Journal* of May 19th, referring to my paper, states: "When called to a case which he diagnoses as an early strangulated hernia, there is only one piece of advice that should be given to a general practitioner: raise the foot of the bed."

It would appear that Mr. Huckell wishes to debar the general practitioner from ever attempting taxis. This is far too sweeping a statement, and cannot go unchallenged. I am strongly opposed to taxis in cases which have not been seen early, but in cases seen by the general practitioner within the first few hours I can see no objection to gentle taxis. There are two reasons why a strangulated hernia becomes more difficult to reduce as time progresses: first, the increasing oedema and distension of the bowel due to venous stasis; and secondly, the contraction of the abdominal muscles. In the early stages these are not marked, and it is this period in which reduction by taxis is most likely to be effective. The only person likely to see the patient at this stage is the general practitioner, and a golden opportunity may be missed if he is debarred from attempting taxis. Mr. Huckell also states: "We have all met with cases where a patch of bowel was more or less necrotic in two or three hours." These, I think, are the very cases in which early taxis by the general practitioner might have avoided such a catastrophe.

The question of taxis is one which will never be decided without the co-operation of general practitioners. Surgeons have no knowledge of the percentage of cases reduced by this method by general practitioners, and until such figures are forthcoming together with their views on the matter, the subject will always be a vexed one. It is a pity that general practitioners have not more opportunities of discussing this and similar subjects with their surgical colleagues; I have no doubt that it would be a great benefit to the profession at large.

Mr. Huckell asks me why I do not operate on non-strangulated hernia patients under the age of 45 with local anaesthesia. First, I find that young subjects are apt to be more frightened, nervous, and restless than the others, and that narcotics do not appear to act so thoroughly (nothing predisposes to bad surgery more than a restless and moaning patient); and secondly, because I prefer general anaesthesia as a rule unless there is some contraindication. Finally, Mr. Huckell refers to the danger of infiltrating the canal in cases of strangulation. I can only say that I have not so far experienced any complications. If the needle is inserted beneath the hernial sac at the top of the scrotum, and slowly passed up the canal, it is quite easy to tell when it impinges on the sac, and the direction can be altered. This method has the advantage of enabling the operation to be carried out without the delay of reinfiltration, plus the time necessary for it to take effect, when the tissues are already exposed and the patient more prone to shock.

I regret that I have had no experience of the injection method of treatment as practised by Mr. Delisle Gray, and, consequently, I am not in a position to criticize it. It would be interesting to have his figures up to date regarding the percentage of cases in which he can carry out this line of treatment, together with his percentages of cures and failures.—I am, etc.,

Hereford, May 19th.

R. WOOD POWER.

Maternal Mortality

SIR,—To Dr. Devlin's valuable suggestions for lowering maternal mortality (May 19th, p. 922) may I add a suggestion which I first made many years ago? Let each death from puerperal fever be followed by a coroner's inquest: Let the jury be two or three obstetric physicians of established reputation—physicians whose duty it would be to inquire into every detail of the conduct of the case. Let the results be published in the Press.—I am, etc.,

Kensington, W., May 20th.

J. McNAMARA, M.D.

Criticism of Ante-natal Work

SIR,—All general practitioners who practise midwifery should return thanks to Dr. Wrigley for his excellent criticism of ante-natal work in the *Journal* of May 19th. It is the best thing I have read for a long time; it should be printed in letters of gold.

Few of us will not agree with the concluding paragraph of his article, where he says:

"Those who practise the art of midwifery have seen that ante-natal supervision as it is being done to-day cannot accomplish all, nor yet half, what has been claimed for it. The pendulum has swung too far. The search for the abnormal has masked the preservation of the normal, and the pregnant woman receives a mixed blessing."

Very true. The propaganda issued by public health authorities, the sensational newspaper articles that have constantly appeared, demanding a stop to be put to puerperal morbidity and mortality, the blame of so much of it thrust upon the attending doctors and nurses, for want of care, cleanliness, and knowledge, how it could all be stamped out if only these women had ante-natal care at public clinics, and could be attended by specially trained doctors—all this has had the undoubted effect of frightening both the pregnant woman and her friends, and the doctors as well.

I have practised midwifery for over forty years, and the only two deaths I have seen from puerperal sepsis occurred in healthy young women who never even had a vaginal examination, and whose full-time, healthy babies were born normally, without any assistance. Midwifery never had any terrors for me until the authorities and the public press "got going," but since I have read so much of the dangers of midwifery, the cases that ought to have Caesarean section or induction done, I am almost frightened to go near a case. I sometimes wish that every confinement in the country could be attended from start to finish by none other than the expert.

I would be immensely interested to see if puerperal morbidity and mortality would then be abolished. Were it so, the world would then know where the blame had lain for so long. Anyway, it is quite clear ante-natal care is doing little or nothing to abolish it.—I am, etc.,

Felton, Northumberland, May 20th

ROBERT A. WELSH.

Vaccine for Acute Gonorrhoea

SIR,—The opening paragraph of Dr. C. E. Jenkins's letter of May 12th (p. 871) indicates that he has missed the chief points of our article. He writes "with some satisfaction at the thought that a useful method of treatment is being more widely employed." In the conclusion of our paper we state that

"the results are disappointing," and again that "whilst admitting the danger of drawing conclusions from such a small number of cases, it would appear that specific gonococcal antibodies . . . have little effect in eradicating the infection from its localized sites in the genital system. This would account for the disappointing results from the use of gonococcal

vaccines, prepared in all manner of ways, in the routine treatment of gonorrhoea."

Although from our results specific gonococcal antibodies, as produced by vaccine, tend to prevent the occurrence of severe acute complications and to shorten the acute stage of the disease, they seem to have little effect in bringing about the destruction of gonococci in their foci in the genitalia. We have yet to be convinced that vaccines deal effectively with the genital focus of infection in gonorrhoea. Although we were able to raise the antibody content of the blood considerably by means of this vaccine in 83 per cent. of the acute cases treated, the results were disappointing. It would appear that, whilst the production of gonococcal antibodies in the blood is usually a simple matter, the eradication of the disease remains as difficult as ever, and therefore we cannot view the results with satisfaction. Subsequent work which we have been doing in the vaccine treatment of patients suffering from chronic gonorrhoea leads us to the same conclusion. We are aware that the use of alkali and acid (and of many other chemicals) in the elaboration of gonococcal vaccines is not novel, as it was recommended by Thomson, but it may be pointed out that in the preparation of the vaccine described by us we keep within the limits of pH 8.8 and pH 5. By this method much of the antigenic moiety of the organism is preserved, whilst its toxic effect is greatly reduced.

We entirely agree with Dr. Jenkins's suggestion that instrumentation in acute gonorrhoea is barbarous, but why accuse us of this procedure?

Opinions on standards of cure vary enormously, but as Dr. Jenkins considers our criteria of cure insufficiently stringent, this should serve to strengthen in his own mind, even more than it did in ours, the conclusion that the presence of antibody in the blood stream does not eradicate the gonococcus.—We are, etc.,

AMEROSE J. KING.

Chemical Factors in Germinal Impairment

SIR,—I was pleased to see in the *Journal* of May 5th, under the heading "Heredity and Mental Deficiency," a letter by Dr. A. C. Hill drawing attention to dangerous possibilities of chemical poisons used for the purpose of contraception. It seems to be generally recognized that the ovum or embryo is susceptible to damage from chemical substances in the maternal environment; but the possibility of damage and impairment of the sperm cell by direct contact with a protoplasmic poison, and of consequent germinal impairment, appears to have received inadequate consideration. At a Central Association for Mental Welfare conference, held in London in 1924, interesting facts were reported as to the influence, both of heredity and environment, in producing degenerative changes in the offspring; the following passage, taken from the printed synopsis of a paper read by Dr. Tredgold on that occasion, is of relevant interest:

"The introduction into healthy plasma of plasma whose developmental potentiality is impaired may have an injurious effect upon posterity extending over many generations."

At the same conference MacBride, dealing with the influence of environment in producing inheritable degenerative changes, referred to the experimental production of sports and monstrosities in certain embryos, quoting Fournier's researches showing, *inter alia*, the production of germinal modifications in response to chemical stimulus."

¹ Tredgold, A. F.: "The Influence of Heredity and Environment in Causing Mental Deficiency." Synopsis of paper read at Central Association for Mental Welfare Conference, May, 1924.

² MacBride, E. W.: "The Influence of Environment in Producing Inheritable Degenerative Changes." Central Association for Mental Welfare Conference, May, 1924.

No doubt much knowledge has been acquired since the time of these researches, though I am not concerned here, in any case, with the precise deductions to be made from Fournier's experiments in relation to physical or mental inheritance. What I do desire to point out is that plenty of information already exists as to the reaction of living cells to, and their possible impairment by, chemical substances—for example, lead. If the chemical substance used as a contraceptive fails to effect completely its lethal object, the possibility of damage sufficient to cause impairment, though insufficient to cause the death of the sperm cell, has to be faced.

I agree with all Dr. Hill's remarks on this subject, and submit that, in the light of existing knowledge, all protoplasmic poisons used for the purpose of contraception—quinine included—must be regarded as potential causes of a germinal impairment that may result in physical or mental defect. However infrequently this factor may operate, the use of chemical substances for the purpose of contraception should be condemned altogether, and the State should take effective steps to terminate the sale of literature, issued attractively under the guise of authority, advocating the adoption of methods that are in fact peculiarly and subtly dangerous and, in my opinion, are in the interests of neither the individual nor the community.—I am, etc.,

Wolverhampton, May 14th.

W. SPENCER BADGER.

Poisoning by Ground Ivy

SIR.—To country and suburban practitioners, so many of whose patients spend their leisure time pottering about their gardens, the subject-matter of Dr. Aitchison Robertson's letter in your issue of May 12th (p. 872) is of considerable interest.

It is not, however, quite clear to which plant reference is made. Ground ivy and common ivy are of course distinct genera, and are classified in quite separate natural orders; ground ivy (*Nepeta glechoma*), a dingy, shade-loving creeper, is a close relative of the more showy catmint (*N. cataria*), and it would be unfortunate if its misdeeds were to be attributed to the common ivy (*Hedera helix*), which adorns so many waste places. Ivy already suffers in reputation in the minds of some, who confuse it with poison ivy (*Rhus toxicodendron*), an entirely separate genus.

The idiosyncrasy by which certain people are affected by certain plants is not constant, and it does not appear that immunity is conferred by repeated small doses of the irritant, but rather the reverse. For example, one may for years handle with impunity *Primula obconica* and then find for some unknown reason that the slightest contact with the plant produces intolerable itching. A market gardener, after years of work, found one summer that he could not handle his tomato plants without setting up eczema of his hands.—I am, etc.,

Bishopbriggs, May 16th.

JAMES B. MILLER.

Occupational Dermatitis

SIR.—Dr. P. B. Mumford, in the issue of the *Journal* of May 12th (p. 860), has so carefully and ably given expression to the major medico-legal difficulties arising in cases of occupational dermatitis that any comments which I can add may well be superfluous. I should, however, welcome an opportunity to state in your columns how warmly I endorse his remarks with regard to the power which is at present given under the Workmen's Compensation Act to the medical referees.

The diagnosis of occupational dermatitis is often one of extreme difficulty, and it is greatly to the credit of

both the certifying surgeons and the medical referees that, in the majority of cases, dermatologists can readily endorse their findings. It is the exceptional cases in which difficulties arise, but these cases are of importance because they result either in injustice to the workmen or in very considerable financial loss to the employers or their insurance companies. It will, I believe, be readily admitted that the present system whereby the ultimate responsibility for adjudication devolves upon a referee who usually has no special training in dermatology is unsatisfactory. Dr. Mumford's suggestion of a "dermatologist panel" is undoubtedly the proper solution of the difficulty, but, if the present system is to continue whereby a referee, without reference to other medical men, can adjudicate in cases of occupational dermatitis, then arrangements should be made for all cases of dermatitis to be dealt with by a special referee who has had wide experience in dermatology and who will be concerned only with dermatological cases.

If this suggestion is not acceptable to the authorities, then the law should be amended so that, in cases where a referee's certificate is disputed, the disputants may have the right to approach the referee, and in asking him to reconsider his decision request him to hear medical evidence in support of their case. The obvious objection to this last suggestion is that the wealthy insurance companies will be able to command a plethora of dermatological opinion which the workman, having no financial resources, cannot combat. In actual practice, however, that objection cannot be sustained. The Workmen's Compensation Act, as at present administered, has, very rightly, a bias in favour of the workman, and no referee will be easily hoodwinked, even if a dermatologist can be found who will knowingly become a participant in an act of injustice.—I am, etc.,

Liverpool, May 14th.

R. M. B. MACKENNA.

Measles Serum for Ulcerative Colitis

SIR.—The following case is, I think, of sufficient interest and importance to justify its being reported.

An otherwise healthy young woman, aged 21, was recently under my care suffering from her third attack (within three years) of ulcerative colitis, which had been going on uninterruptedly for just over three months. Her previous attacks were less severe, and lasted approximately one month and two months respectively.

On expectant treatment she was doing badly, passing blood and mucus about six times per day, and an ileostomy was contemplated. As her brother, who had been in contact with her, developed a typical attack of measles, it was deemed advisable to immunize her, as she had not previously had this disease. She was accordingly given 12 c.cm. of convalescent measles serum intramuscularly into the thigh. Within forty-eight hours there was marked improvement in her condition, both local and general, and within a week the blood and mucus, which had before this time increased sufficiently to cause some concern, entirely disappeared and her motions became perfectly normal.

This I cannot attribute entirely to coincidence, when one knows of other cases of ulcerative colitis that have cleared up equally dramatically after a blood transfusion. I would therefore ask those who have an opportunity of seeing and treating a number of cases of this very distressing, though fortunately rare, disease, to try this method of treatment and publish their results.

It is my belief that ordinary human serum, not necessarily from a convalescent measles patient, would act equally well, as it is probable that this disease is due to some, as yet unknown, blood deficiency.

I should be grateful to have your readers' views on this interesting case.—I am, etc.,

London, W.5, May 14th.

L. CARLYLE LYON, M.B.

Obituary

O. J. KAUFFMANN, M.D., F.R.C.P.

Emeritus Professor of Medicine, University of Birmingham; Consulting Physician, Queen's Hospital, Birmingham

Professor Otto Jackson Kauffmann of Birmingham died on May 15th from cerebral thrombosis at the age of 71. Many who read this notice will be surprised at his age, for right up to a very few days before his death he exhibited all the physical and mental attributes of a very much younger man.

Educated at Owens College, Manchester, and St. Mary's Hospital, London, Kauffmann registered as M.R.C.S. Eng. and L.R.C.P. Lond. in 1885, and qualified for the gold medal of the London M.D. in 1888. He was admitted to the Fellowship of the Royal College of Physicians in 1910. His professional activities were devoted to Birmingham, where, in addition to a large consulting practice, he was associated for over forty years with the Queen's Hospital, Mason University College, and later the University. After filling resident posts at Owens College, Manchester, the Brompton Hospital, London, and the Seamen's Hospital, Greenwich, he joined the visiting staff of Queen's Hospital in 1892 as physician for out-patients, and in the following year was appointed professor of pathology at Mason University College. In 1897 he became honorary physician to the hospital, and after twenty-six years' service in that capacity was elected consulting physician. While with most men such an appointment means retirement from the hospital it was not so with Kauffmann, for up to a few days before his death he visited the wards almost daily, discussing puzzling cases, and always ready to place his wide experience at the disposal of his younger colleagues.

At the University of Birmingham Kauffmann will best be remembered as professor of medicine from 1913, to 1926, although he had previously held the chair of pathology at Mason University College from 1893 to 1897. For two years (1922 to 1924) he was chairman of the Clinical Board, and throughout his long association with the Medical School he took a prominent part in its development. His work in this respect was recognized by his appointment as *emeritus* professor of medicine on his retirement from the active duties of the chair. Although Kauffmann's interest in medicine was widespread, he always had a leaning towards neurological problems, and in 1900 delivered the Ingleby Lecture on "The Common Neuroses of Children."

Professor Kauffmann was elected by his colleagues in 1921 as president of the Association of Physicians, which met that year in Birmingham. During the war he had been attached as lieutenant-colonel R.A.M.C. to the 1st Southern General Hospital, where he worked indefatigably, and at the same time carried out his teaching and other duties at the University and the Queen's Hospital. A member of the B.M.A. since 1892, he was vice-president of the Section of Pathology in 1899, vice-president of the Section of Paediatrics in 1906 at Toronto, and president of the Section of Diseases of Children in 1911.

Professor Kauffmann was a most gifted and cultured man. Philosophy, literature, and music, no less than medicine, had for him an attraction which is seldom found to the same degree in a member of our profession. It is a matter of regret that one so eminently fitted both by education and by great critical acumen for writing on medical subjects should have left so little behind. He was a good violinist, a keen yachtsman, and a fearless rider to hounds. He led a comparatively quiet and methodical life, rose early, and as far as he could avoided social functions which threatened to keep him up to a late hour. He married rather late in life, and his married life was wonderfully serene and happy. He leaves a widow, two sons, and a daughter.

FRANK KIDD, M.Ch., F.R.C.S.

Late Surgeon to the London Hospital

We regret to announce the death of Mr. Frank Kidd, the well-known surgeon and urological specialist, which occurred at his country house, Bransbury Mill, Barton Stacey, on May 12th.

Francis Seymour Kidd was a son of the late Dr. Joseph Kidd, and was born at Charlton, Kent, on March 30th, 1878. Educated at Winchester in 1896-6, and later at Trinity College, Cambridge, he went to the London Hospital, and was awarded the surgical scholarship there in 1902. He qualified in 1903, taking in that year both the diplomas of M.R.C.S., L.R.C.P. and the Cambridge B.Ch. degree. After doing several house appointments at the London Hospital he became demonstrator of anatomy in the medical college, and took the F.R.C.S. in 1905. The appointment of surgical registrar followed in 1906, and afterwards he did post-graduate work in Berlin and elsewhere. The months he passed in Berlin made a great impression on him, and he was always a great admirer of German urology and urologists. He felt that there was no better start for a urological career than six months or a year spent at some German clinic. One of the last of many foreign professional distinctions he received, and one that he prized very highly, was his election as a corresponding member of the Berliner Urologische Gesellschaft in 1931.

Frank Kidd became assistant surgeon to the London Hospital in 1910, and in the same year published his first important work—*Urinary Surgery*. This book is a review of the state of urinary surgery at that time, and as such can still be read with pleasure and profit. It was the first of a long series of writings, and differs from the others in that it was of necessity completed before the author had much operative experience, whereas all his later works were essentially practical and the result of his own ripe experience. In his introduction to the book he pointed out that the day for treating symptoms was passing away, and that with the improvement in the technique of ureteric catheterization, the introduction of x rays, the development of bacteriology, and the improvements in the surgery of the prostate, it was now possible to discover the cause of most urinary symptoms, and to treat the cause, when found, with safety.

He was a prolific author, and many of his writings were on the subject of venereal disease. He started a genito-urinary department at the London Hospital, which included a section for the treatment of venereal disease. At first only men were treated, but later the department was enlarged to admit women and children. It had always been his firm conviction—and, now, one that almost everybody would admit—that no urologist could hope to be successful in the fullest sense, or even competent, unless he was fully acquainted with venereal disease and diseases of the urethra. His second book, *Common Diseases of the Male Urethra*, published in 1917, is perhaps his best-known work, and it certainly showed Kidd at his best as a clinician and teacher. It is a simple exposition of the lines on which urethritis in the male can be treated successfully, and it must have guided many beginners in the treatment of gonorrhoea, and prevented them from doing harm. Though the treatment advocated by him in 1917 may not nowadays be universal, it would be difficult to deny that perhaps 80 per cent. of all cases would be cured by the methods laid down in his book, and it was not Kidd's intention to do more than that in a volume written primarily for the inexperienced. He had no illusions about the difficulties of treatment in certain cases, but he deliberately made little or no attempt to deal with these in his book. In 1920 he published *Common Infections of the Female Cervix and Urethra*, in collaboration with Dr. A. Malcolm

Simpson, and in 1924 his last work, *Common Infections of the Kidneys*—both of them very popular books. In addition to his major works he wrote frequently for the journals, and no year passed without some communication from his pen. In these contributions there was usually something new, and the subjects he chose showed the diversity of his interests in his own branch of surgery, while the way in which he treated them illustrated the fact that he was always learning something new from his increasing experience. It is curious that he hardly wrote anything at all about the prostate and prostatic surgery, since he was particularly skilled in this branch of urology, and in his later years, after a trial of many different methods, had gone back to the simplest form of enucleation through a small incision without inspection of the cavity after enucleation.

Kidd had been elected surgeon to the London Hospital in 1917, but owing to ill-health he was compelled to resign in 1920. In addition to this appointment he was consulting surgeon to St. Paul's Hospital, and in 1921 he was made M.Ch.Camb. He was particularly skilful in using the special instruments required in his branch of surgery with the minimum of pain and discomfort to the patient. He was also a clever and dextrous surgeon, who was never disturbed or unnerved when things went badly. The only thing that upset his habitual calm during an operation was an unnecessary question or conversation between onlookers. In the immediate post-operative period he probably worried more than most surgeons, since it was his nature to visualize all the complications and disasters of any operation he had performed, even though he must have known that he had done it so skilfully that the chance of these was reduced to a minimum. There is another side to his character that has little to do with his surgical skill—this is perhaps not so widely known—and it is not surprising that his patients accorded to him a devotion not often given even to the most successful surgeon. He was a good listener, and always sympathetic with his patients, and had much of the good general practitioner's skill in curing them, even when there was no organic lesion. In the course of his practice as a urologist and specialist in venereal diseases he saw many patients with functional symptoms, and he probably has more grateful patients among this class even than among those who were cured by his surgical skill.

He was president of the Urological Section of the Royal Society of Medicine in 1927 and 1928, and was widely known in America and on the Continent, as his many academic honours show. He was a member of the International Society of Urology, a member of the Association Française d'Urologie, a corresponding member of the American Association of Genito-urinary Surgeons, an honorary member of the American Urological Association, a corresponding member of the Berliner Urologische Gesellschaft (as already mentioned), and a corresponding academician of the Royal Medical Academy of Rome.

At Winchester he was in the association football eleven, and later played hockey for the South and was reserve for England. His chief recreations were shooting and fishing. He is survived by his widow and three sons.

MEREDITH YOUNG, M.D., D.P.H.

Dr. Meredith Young, who died on May 7th, will be remembered as Cheshire's second medical officer of health. The first was Dr. Vacher, who did the spade work. Upon Meredith Young, when he "took over," fell the task of improving, modifying, stabilizing, and amplifying an already going concern. His temperament was fitted for the work, a heritage perhaps from a mixed Huguenot and Highland ancestry. He was gentle, subtle, and willing—when he might—to be all things to all men.

We sometimes used to think he would have been better understood had he been more decisive. Yet when public policy required he could be firm. Even then his views were conveyed in a manner so conciliatory that the loser lost nothing of self-respect. Public policy! It was that which was the determining factor of his actions. He was strong when he was clear upon what was the true line in the public interest. It was when he was uncertain of it that his conduct of affairs seemed hesitant. In his early days he was medical officer of health for Stockport, Crewe, Brighouse, Halifax, and Marylebone, and in 1909 he came to Chester as county medical officer of health, still a young man and full of promise. During the first lustrum, perhaps the first decade, the promise was fulfilled, but the course before him was arduous and took a heavy toll of his physique and morale. A county public health budget in 1909 of £4,000 grew in the years that followed to the present enormous total of a quarter of a million, and with it grew the complexities and anxieties of his office. His health progressively weakened, till in 1932 he felt compelled to retire. He had early clinical interests, and besides his M.D. had taken the Edinburgh Mastership of Surgery. He had considerable experience in fevers, and had written about scarlatina; and was the author of a volume on the mentally defective child. As the Cheshire staff mounted from the original number of two officers to the eventual six school medical officers, three tuberculosis officers, six school dentists, two ophthalmic surgeons, forty health visitors, and two assistant medical officers of health, he found himself sometimes at variance with the British Medical Association's views as to scale of pay. This led to his resignation from the Association. But at a later stage he concurred with the Panel Committee in the opinion that the child welfare centres should be staffed by general practitioners, a system which was accepted by the County Council and still holds the field. And in other respects his relations with the profession were often of the happiest. He was a president of the Chester and North Wales Medical Society and, in 1931, president of the Association of County Medical Officers of Health. Throughout his career he was a believer in the popular teaching of ambulance work, and his efforts were recognized; in May, 1926, he was invested at the chapter of the Order of St. John, in Clerkenwell, as an Esquire of that ancient body. He had a trained and accurate mind—he was a barrister-at-law of Lincoln's Inn—but had not the tough casing which instruments of precision require if they must stand hard wear.

L. J. P.

Dr. REGINALD LATIMER WELLINGTON GREENE died at his home at Stratford-on-Avon on May 12th after a short illness, at the age of 81. He studied at Queen's College, Belfast, and at Edinburgh, qualifying L.R.C.P. and S.Ed. in 1880. Shortly afterwards he settled in Stratford-on-Avon, and quickly took an active interest in medical and municipal affairs in the town. For over forty years he was honorary medical officer of the hospital, and in 1932 was appointed honorary consultant on his retirement, a position which he held until his death. During all these years Dr. Greene kept a lively interest in the work and welfare of the hospital; as chairman of the medical board his advice and help has been much valued by his colleagues. He was a staunch supporter of the B.M.A., and always advised his younger colleagues to become members; he had been a member for forty-nine years, and specially interested himself in the charities, being a life governor of Epsom College. He was a past chairman of the Warwick and Leamington Division of the B.M.A. In national health insurance affairs he was one of the original members of the Local Medical and Panel Committee, of which he was vice-chairman and representative on the Medical Service Subcommittee of the Warwickshire Insurance Committee. His interests were not confined only to his profession, as he was mayor of Stratford-on-Avon for

three years, a J.P., and alderman. Among his other public offices he was vice-chairman of the Executive Trustees of the Shakespeare Trust, trustee of the Municipal Charities, and a secretary of the Shakespeare Club. It was owing to his suggestion that the annual unfurling of the national flags takes place on Shakespeare's birthday. Freemasonry also had a strong hold on his activities; he was W.M. of the Swan of Avon Lodge, Prov. G.S.B., and F.P.G.W.S. From 1903 he had been charity steward. Dr. Greene held high ideals of the etiquette and ethics of the profession, and always strove to uphold these, especially for the rights of the medical practitioner. The large attendance at the funeral service, at the Holy Trinity Church, of his fellow townspeople and the many representatives of all the above-named public bodies testified to the esteem and respect with which he was held. His life may be summed up in "service to others." He is survived by his widow and daughter. His only son, who was principal medical officer at Sarawak, died at Lahuan in 1919.

Dr. JAMES PATRICK FENNELL, who died on May 9th in his eighty-fourth year, belonged to the past generation of medical practitioners. He qualified from Dublin in 1878 as L.R.C.P.I. and L.M., L.R.C.S.I.; before the whole outlook in the practice of medicine was revolutionized by the first bacteriological discoveries of the 'eighties; yet his knowledge of his profession was sound, as he combined his vast experience with the new developments that were constantly taking place. Commencing in the provinces, he eventually settled in the Dalston district of London; he practised there for over thirty years, retiring some ten years ago to Eastbourne, where he died. He refused to undertake national health insurance work, and was one of the very few non-insurance practitioners in his area. Dr. Fennell (writes B.H.) was a courteous and lovable man, and had endeared himself to all who came in contact with him. He was most generous to charities and to strangers, and it afforded him pleasure to give, although there was little left for himself. I shall always cherish his memory. He leaves a widow (formerly a London Hospital nurse), who devotedly nursed him during his illness.

We regret that in the obituary of Dr. Daniel Falconer Riddell, published last week (p. 924), his name was incorrectly stated.

Universities and Colleges

UNIVERSITY OF LONDON

A meeting of the Senate was held on May 16th, with the Vice-Chancellor (Professor L. N. G. Filon, D.Sc., M.A., F.R.S.) in the chair.

Dr. L. P. Garrod was appointed to the University Readership in Bacteriology at St. Bartholomew's Hospital Medical College, as from October 1st, and Dr. G. R. Cameron to the University Readership in Morbid Anatomy at University College Hospital Medical School, as from April 1st.

The degree of D.Sc. in Physiology was conferred on Dame Anne Louise McIlroy, M.D., University Professor of Obstetrics and Gynaecology at the London School of Medicine for Women.

The Dunn Exhibitions in Anatomy and Physiology for 1934 were awarded to A. Cohen (University College) and A. J. Bernfeld (Middlesex Hospital Medical School).

UNIVERSITY OF LIVERPOOL

The following awards have been made in the Faculty of Medicine: *Gold Medal for Medicine*, J. K. B. Waddington; *proxime accessit*, Margaret F. Procter. *Clinical School Exhibition (Clinical Medicine)*, A. J. McCall. *A. C. Rich Prize (Clinical Medicine)*, E. W. Jones. *Gold Medal for Surgery*, A. C. Brewer. *Derby Exhibition (Clinical Surgery)*, J. G. Sheldon. *Gold Medal for Obstetrics and Gynaecology*, A. J. McCall; *proxime accessit*, Margaret F. Procter. *Robert Gee Prize (Diseases of Children)*, V. K. Drennan. *Lyon Jones Scholarship for Anatomy and Physiology*, R. R. Hughes; *proxime accessit*, H. Hughes. *Torr Gold Medal for Anatomy and George Holt Medal for Physiology*, R. R. Hughes. *John Rankin Exhibition (Practical Anatomy)*, divided between R. R. Hughes and H. Hughes.

UNIVERSITY OF DUBLIN TRINITY COLLEGE

The fourth series of John Mallet Purser Lectures will be delivered in the Department of Physiology (Medical School) on Tuesday and Thursday, June 12th and 14th, at 5 p.m., by Professor C. U. Ariens Kappers, Sc.D. (Director of the Institute for Brain Research, Amsterdam). Professor Kappers's subject for the first lecture will be "The Differences in the Effects of Various Sensations on the Structure of the Nervous System," and for the second lecture "The So-called Semitic and Aryan Peoples in the Near East." The lectures are open to the public.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

A meeting of the Royal College of Surgeons of Edinburgh was held on May 15th, when Dr. A. H. H. Sinclair, President, was in the chair. The following candidates, having passed the requisite examinations, were admitted Fellows: P. J. Fogarty, S. J. Campbell, S. Davidson, D. J. Davies, M. D. A. Evans, J. M. Fosbrooke, K. Hunter, M. L. Kaufman, D. H. Klugman, J. Lawrie, C. R. Macdonald, D. C. Mackenzie, J. C. Mackenzie, A. I. L. Maitland, I. M. Orr, L. C. Palmer-Jones, J. Polonsky, J. H. G. Robertson, B. P. Robinson, Dorothy M. Satur.

The Henry Arthur Dalziel Ferns Bursary was awarded, after a competitive examination in organic chemistry in its application to medicine, to J. Schlosser.

The Bathgate Memorial Prize was awarded, after a competitive examination in materia medica and therapeutics, to G. B. Drummond.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

Parliament stands adjourned till May 29th.

The Finance Bill was read a second time in the House of Commons on May 16th by 290 to 55. During the debate Mr. David Grenfell said the Opposition was grateful for the Government's action in abolishing the duty on imported insulin, which would relieve nearly 250,000 persons. The Government spokesmen did not allude to this provision in the speeches. After the division a group of Conservatives gave notice that in committee they would move to delete Clause 5, which contains the proposal about the insulin duty.

The Cotton Manufacturing Industry (Temporary Provisions) Bill and the Mines (Working Facilities) Bill were read a second time by the House of Commons on May 17th.

The Royal Assent was given in the House of Lords, on May 17th, to the Marriages (Extension of Hours) Act, the Supply of Water in Bulk Act, the Firearms Act, the Registration of Births, Deaths, and Marriages (Scotland) (Amendment) Act, the Water Supplies (Exceptional Shortage Orders) Act, the Protection of Animals Act, the Cambridge University and Town Waterworks Act, and to other Acts.

The House of Commons, on May 18th, read the Birmingham United Hospitals Bill a third time.

Sir John Gilmour announced, on May 17th, that the Government had decided to introduce a Bill to enable licensing justices to grant, at their discretion, an extension of permitted hours for a part of the year only, from 10 p.m. to 10.30 p.m. The Bill would apply to Wales.

An Order extending without time limit the present import duties on iron and steel was laid on the table of the House of Commons on May 17th.

Fees for Emergency Treatment

Text of Proposed Clause in Road Traffic Bill

With Sir Francis Fremantle in the chair and Lord Luke representing King Edward's Hospital Fund, a conference of medical members of Parliament, Peers, and others at the House of Commons, on May 16th, approved a new clause which will be moved as an addition to the Road Traffic Bill in standing committee. This clause has been put down in the

names of Sir Francis Fremantle, Mr. J. C. M. Guy, Colonel Crookshank, and Mr. S. Storey. Its text is as follows.

1.—Where medical or surgical treatment or examination is immediately required as the result of bodily injury (including fatal injury) to any person caused by, or arising out of, the use of a motor vehicle on a road, or in a place to which the public have a right of access, and the treatment or examination so required (in this section referred to as "emergency treatment") is effected by a registered medical practitioner, the owner of the vehicle shall, on a claim being made in accordance with the provisions of the next succeeding section, pay to the practitioner, or, where emergency treatment is effected by more than one practitioner, to the practitioner by whom it is first effected, (a) a fee of 12s. 6d. in respect of each person in whose case the emergency treatment is effected by him; and (b) a sum, in respect of any distance in excess of two miles which he must cover in order to proceed from the place whence he is summoned to the place where the emergency treatment is carried out by him and to return to the first-mentioned place, equal to sixpence for every complete mile and additional part of a mile of that distance.

2. Where emergency treatment is carried out in a hospital (that is to say, an institution, not being an institution carried on for profit, which provides medical or surgical treatment for in-patients) the provisions of the foregoing subsection with respect to the payment of a fee shall have effect with the substitution of references to the hospital for references to a registered medical practitioner.

3. Liability incurred under this section by the owner of a vehicle shall, where the event out of which it arose was caused by the wrongful act of another person, be treated for the purposes of any claim to recover damage by reason of that wrongful act, as damage sustained by the owner.

4. A policy of insurance or a security in respect of third-party risks shall not be deemed to comply with the requirements of Part II of the principal Act unless the owner of the vehicle to which it relates is specified therein for the purposes of paragraph (b) of subsection (1) of section 36, or of section 37, of the said Act, as the case may be, and, notwithstanding anything in the proviso to paragraph (b) of subsection (1) of the said section 36, any liability which may be incurred under this section by the owner shall be deemed to be a liability to be covered under that paragraph.

Provisions as to Claims for Payment

1. A chief officer of police shall, if so requested by a person who alleges that he is entitled to claim a payment under the last foregoing section, furnish to that person any information at the disposal of the chief officer as to the name and address of the owner and the identification mark of any motor vehicle which that person alleges to be a vehicle out of the use of which the bodily injury arose.

2. A claim for a payment under the last foregoing section may, if the owner of the vehicle is present at the time when the emergency treatment is effected, be made by oral request to him, and if not so made must be made by request in writing served on the owner within (seven) days from the day on which the emergency treatment was effected.

3. A request in writing must be signed by the claimant or, in the case of a hospital, by an executive officer thereof, must state the name and address of the claimant, the circumstances in which the emergency treatment was effected, that it was effected by the claimant, or, in the case of a hospital, in the hospital, and, where it was effected by more than one practitioner, that it was effected first by the claimant.

4. A request in writing may be served by delivering it to the owner or by sending it in a prepaid (registered) letter addressed to him at his address as specified in the particulars registered in relation to the vehicle under section 6 of the *Motor Act, 1920*.

5. A sum payable under the last foregoing section shall be recoverable as if it were a simple contract debt due from the owner of the vehicle to the practitioner or the hospital.

6. A payment made under the last foregoing section to a practitioner or hospital shall operate as a discharge, to the extent of the amount paid, of any liability of the owner of the vehicle or of any other person to pay any sum in respect of the expenses or remuneration of the practitioner or hospital of or for effecting the emergency treatment.

7. A payment under the last foregoing section shall not be deemed to be a payment by an authorized insurer or owner for the purposes of subsection (2) of section 36 of the principal Act.

Tests for Motor Drivers

In Standing Committee on the Road Traffic Bill, on May 17th, Clause 5 was considered. This clause concerns "Tests of competence to drive of new applicants for licences and of offenders ordered to be tested."

Sir ERNEST GRAHAM-LITTLE moved to insert words providing that such persons should have "passed the prescribed psycho-physical examination for fitness" and subsequently the prescribed test of competence to drive." Sir Ernest said the tests he suggested had been studied and applied by the Institute of Industrial Psychology, whose president was Lord Macmillan. Experience had been gained with tests in other walks of life. Of 106,000 factory accidents in a year, 66,000 were considered by experts observing them to be due to

conditions in the personnel: Fatigue, rush hours, bad ventilation, poor lighting, and emotional states all entered into the production of accidents. What was the ratio of the human factor in accidents on the roads? Where expert examination had been made it had been conclusively shown that the same causes operated in road accidents as in factory accidents, and that the human factor was far the more important. The director of the Institute of Industrial Psychology had given Sir Ernest a proposed category of tests. The first class of tests determined the capacity of response to an emergency. The simple reaction time, tested by the person pressing on levers when lights came into view, varied from half a second to a second and a half. The second test was of reaction time confronted with distraction, which materially increased the time. The third test was of vigilance. The person tested must remember something about a film which was exhibited as well as press the lever when the lights went up. The second group of tests was for ability to make rapid and accurate judgement of the size of objects, the space between objects, and of distances and speeds, by a simple and efficient apparatus. The third class tested vision, both for acuteness and the condition of the eye muscles. It did not suggest a medical test. That would be expensive. Experience showed that gross disabilities, as of hearing, came out in the application of the physical tests. The correlation between the scores made in tests at the Institute and the accident records of persons tested had been singularly close. He pointed out how the "braking distance" of cars varied with the reaction time of the driver as well as with the velocity of the car. If the car was going thirty miles an hour, it would travel an additional thirty feet during the reaction time of the average driver. The greater part of the research on these tests had been done in the United Kingdom, but they had been more largely applied in France, the United States, and in Germany. In Paris the General Transport Company, which was responsible for trams and omnibuses, had applied tests which had decreased accidents by 30 per cent. and had saved 1,500,000 francs a year in wear-and-tear of vehicles. A professor of statistics in the University of London was of opinion that the number of accidents in this group was sufficient to indicate the trend. The Institute had other tests, but he suggested restriction to the three types of tests he had indicated, and not to apply the test for road behaviour which they did now. He proposed that the present road test should be combined with the tests he had described. They could be carried out by persons who were already drivers, who could learn the technique in a fortnight if of average intelligence. Apparatus to carry out the tests would cost about £60 in each centre.

Opinions on the Amendment

Sir JOSEPH LAMB said the committee would err in putting specific tests into an Act of Parliament. They should leave the Minister to issue regulations about such tests.

Mr. LOVAT-FRASER supported the amendment. Mr. LEWELLYN JONES suggested that the Minister should arrange for the drivers of public service vehicles in a specified area to be subjected to the tests which had been described. The Ministry would then soon be able to say whether it was advisable to apply the same tests to all public service drivers and ultimately to all persons applying for a driver's licence.

Sir FRANCIS PREMANTLE agreed that this was a question for the regulations which were to be issued by the Minister, who should take into account the reaction factor. Sir Francis thought the tests might be worked into the regulations. Sir Ernest Graham-Little's amendment had enabled the committee to get down to the root of the trouble with which the Bill dealt—the accidents not due to maliciously careless driving. A man's reaction time made all the difference at a critical moment.

Mr. STANLEY, Minister of Transport, said he did not detract from the value of the experiments which had been carried out, nor deny possible greater advances in future, but the committee could not possibly accept this amendment. Its result would be that a man could be kept off the roads for ever without appeal against an admittedly experimental system. Mr. Stanley added that he had talked with the director of the Institute of Industrial Psychology, who definitely denied that it would be possible to institute at once a system of this kind. The experiments had shown the possibility of grading drivers, but nothing in the evidence

would enable the Ministry of Transport to determine whether, by the application of these tests, they could, before a man had ever been in a car, find out whether he would be a safe driver. Mr. Stanley said he had turned for advice to the Medical Research Council. It had carried out extensive experiments in this matter, and told him that so far as distinguishing between the good driver and the less good driver was concerned the experiments had already proved themselves. The Council also told him definitely that in respect of application of a test of this kind before a man was allowed to go on the road at all, the experiments had not revealed that this matter had reached a state of practical utility. He had told the director of the Institute that he would consider any suggestions from him about tests which might be incorporated in the ordinary test to be given to drivers under this Bill. He would watch the future of the experiments with interest, but to make the tests compulsory now would crush them in their infancy, and stop what might in future become a valuable development.

The committee rejected Sir Ernest Graham-Little's amendment without a division.

Visual and Auditory Defects

On the motion that Clause 5 stand part of the Bill, Mr. LOVAT-FRASER asked whether the Minister, in drawing up the Bill, would decide how far old age, colour-blindness, and deafness affected applicants for licences. Sir GIFFORD FOX asked if it was possible to have a test for night driving. At present nothing was done to disqualify a person whose eyes were right in the daytime but could not see at night. Mr. STANLEY said the last question was interesting, and he would consider it. He was already able to prescribe tests for physical defects, but was not entitled to say that no man who was deaf or colour-blind might have a licence. It might be impossible for some persons to pass the test owing to physical disability of that kind.

The clause was added to the Bill with slight amendments.

Oysters.—Sir HILTON YOUNG told Sir M. SUTER, on May 16th, that his attention had been drawn to a recent case before the King's Bench Division in which evidence had been given that typhoid fever had been contracted as a result of eating oysters. It was subsequently decided that the oysters as supplied by the Fishing Company were not shown to be contaminated, but he was communicating with the local authority concerned. Replying to Sir John Pybus, on May 17th, Mr. ELLIOT said he had learned with satisfaction that the cleansing of oysters at Brightlingsea had been initiated and was proceeding with excellent results. The technical officers of his Department would always be ready to advise and assist local authorities who might be disposed to follow the lead given by the Brightlingsea Urban District Council.

Infant Mortality.—Replying to Mr. Rhys Davies on May 17th, Sir HILTON YOUNG gave the following figures concerning general and infant mortality in England and Wales:

Year	General Death Rate per 1,000 Estimated Population	Infantile Mortality Rate (namely, deaths under 1 year of age per 1,000 live births)
1929	13.4	74
1930	11.4	60
1931	12.3	68
1932	12.0	65
1933	12.3	64

Animal Experiments.—In reply to Mr. Groves, on May 17th, Mr. DOUGLAS HACKING stated that the "University Medical and Scientific Departments, Edgbaston, Birmingham," were already registered for the performance therein of experiments on living animals. He had not received any communication from the university authorities on the inclusion of the new medical school buildings in the registered premises. Mr. Hacking explained that a conflicting reply given to Mr. Groves on May 17th by Sir John Gilmour was made under the impression that Mr. Groves referred to Birmingham General Hospital.

Control of Opium Traffic.—Sir JOHN SIMON told Mr. David Grenfell, on May 18th, that the Opium Committee of the League of Nations had not issued a report on the official opium monopoly alleged to be established in the north-eastern

provinces of China under Japanese occupation. The Council of the League last January adopted a recommendation of the Opium Advisory Committee that the attention of the chief producing and manufacturing countries should be drawn to the necessity of supervising strictly any application for admission of narcotics into the territory of Manchuria and Jehol. The British Government had complied with the recommendation and with its obligations under the Hague Opium Convention.

Financing of Hospital Extension.—Sir ROBERT GOWER, on May 18th, asked whether the Minister of Health proposed to provide public funds for hospital extension on the lines recommended in the report of the Voluntary Hospitals Commission. Sir HILTON YOUNG answered that he knew of the recommendation made in the report of 1925, but the situation had been altered by the Local Government Act, 1929, which conferred wide powers on county councils and county borough councils for provision of hospital accommodation, including power to make subscriptions or donations to voluntary hospitals. It was undesirable, in view of these powers, to provide assistance by direct Exchequer grant.

Antitoxin Inoculations.—Mr. GROVES asked, on May 18th, whether the Minister would stop the issue to the public by medical officers of health of statements that the substances used in inoculation of antitoxin were harmless. Mr. Groves referred to changes which were known to take place in the blood of certain people through such inoculation. Sir HILTON YOUNG replied that such changes were intended to be beneficial, and were so in fact with rare exceptions. He saw no reason for taking such steps as Mr. Groves suggested.

Medical Expenditure by Public Assistance Committees.—Sir HILTON YOUNG states that no figures are available by which he could estimate the additional expenditure incurred by public assistance committees in England and Wales for medical services and treatment, including maternity services, to unemployed persons who had ceased to be eligible for medical benefits under the National Health Insurance Acts. Replying on the same subject to Mr. David Grenfell, on May 17th, Sir HILTON YOUNG said he would communicate with public assistance authorities in Glamorganshire for information respecting that county. A general inquiry would be impossible.

Notes in Brief

The report of the Scientific Committee appointed by the Economic Advisory Council to consider the incidence of milk-borne diseases has been presented to Parliament. Mr. Baldwin stated that it would be available shortly.

The average number of casualties in receipt of poor relief in England and Wales in 1933-4 was 14,319. On January 1st, 1934, 95.9 per cent. were men, 3.7 per cent. were women, and 0.4 per cent. children under 16 years of age.

Medical News

The Bolingbroke Lecture will be delivered before the South-West London Medical Society at the Bolingbroke Hospital; Bolingbroke Grove, Wandsworth Common, S.W., on Wednesday, June 6th, at 9 p.m., by Mr. Comyns Berkeley, on "Some Things I Have Learnt." All medical practitioners are welcome.

A Chadwick Public Lecture on "Simples and Herbs" will be delivered by Mr. E. A. Bowles at Chelsea Physic Garden, Swan Walk, Chelsea, S.W., on Thursday, June 14th, at 5 p.m., when Sir William J. Collins will occupy the chair. Admission free, without ticket.

The Buckston Browne annual banquet of the Harveian Society of London will be held at the Connaught Rooms, Great Queen Street, on Thursday, June 14th, at 7.30 for 8 p.m.

The Royal Society of Tropical Medicine and Hygiene will hold a conversation at 26, Portland Place, W., on Thursday, May 31st. Reception at 8.30 to 9 p.m. by the president, Major-General Sir Leonard Rogers, and Lady Rogers. Refreshments, music, dancing. Tickets 5s. each for Fellows and their guests, on application to the secretary, 26, Portland Place, W.1.

The annual general meeting of the London and Counties Medical Protection Society Limited will be held at Victory House, Leicester Square, W.C., on Wednesday, May 30th, at 4 p.m., to receive and adopt the annual report and balance sheet, to elect officers and auditors, to fill vacancies on the council, and to transact other business.

The Fellowship of Medicine (1, Wimpole Street, W.) announces that Dr. Clark-Kennedy will give a lecture-demonstration on functional heart disease at 11, Chandos Street, W., on May 29th at 2.30 p.m. The next lecture, on poor circulation, will take place on June 5th. A week-end course in medicine and surgery will be given at St. Mary's Hospital, Plaistow, on Saturday and Sunday, June 2nd and 3rd. The course will consist of lectures and demonstrations and will occupy the whole of both days. On June 9th and 10th there will be a course in obstetrics at the City of London Maternity Hospital. Other forthcoming courses include two similar courses in medicine, surgery, and the specialties at the Prince of Wales's Hospital, June 11th to 23rd and June 25th to July 7th; and a week's course in proctology at St. Mark's Hospital, June 11th to 16th. On Saturday, June 9th, Mr. Hamilton Bailey will demonstrate surgical cases at the National Temperance Hospital. A debate will take place on Wednesday, May 30th, at 8.30 p.m., at 26, Portland Place, W. The motion will be, "That in the absence of complications, surgical interference in cases of gastric and duodenal ulcer is unnecessary." Lord Moyrhan will take the chair. The motion will be proposed by Dr. A. F. Hurst and seconded by Mr. Mortimer Woolf, while Dr. Robert Hutchison, seconded by Mr. Herbert Paterson, will oppose the motion. All members and associates of the Fellowship and their medical friends are cordially invited to be present at this debate.

The fourteenth annual International Neurological Congress will be held at La Salpêtrière, Paris, on June 5th and 6th, when the following subjects will be discussed: the anatomy, physiology, and pathology of the mesodiencephalic vegetative nervous system, introduced by Laruelle of Brussels (anatomy), Tournay of Paris (physiology), and André-Thomas and Lhermitte (pathology); congenital ectodermal dystrophies, by von Bogaert of Antwerp; and syphilis of the cerebellum, by Christophe of Paris. Further information can be obtained from the general secretary, Dr. Crouzon, 70 bis, Avenue de Jéna, Paris, 16E.

The National Smoke Abatement Society will hold a special conference in London on Friday, June 8th, to consider the question of smokeless fuels for open grates. The problem is to be discussed not only from the technical point of view of the fuel producer, but from the standpoint of the grate designer and the housewife. The development and marketing of smokeless solid fuels will also come under review. Those interested can obtain copies of the agenda and invitations from Mr. Arnold Marsh, general secretary of the society, 23, King Street, Manchester, 2.

The American Association for the Study of Goiter will meet this year in Cleveland, Ohio, on June 7th, 8th, and 9th, just before the annual meeting of the American Medical Association. The honorary secretary is Dr. J. R. Yung (Terre Haute, Indiana, U.S.A.). The principal subject for discussion is hyperthyroidism.

The fourth International Congress for First Aid will be held in Copenhagen from June 11th to 16th, under the patronage of H.M. The King of Denmark.

In our advertisement columns this week appears a notice inviting applications for the University Chair of Obstetrics and Gynaecology, tenable at the London (Royal Free Hospital) School of Medicine for Women. The salary is £2,000 a year, and applications (twelve copies) must reach the Academic Registrar, University of London, S.W.7, by the first post on June 19th.

Professor F. E. Tylecote, M.D., F.R.C.P., has been placed on the commission of the peace for the City of Manchester by fiat of the Chancellor of the Duchy of Lancaster, dated May 16th, 1934.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, Aitology Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westcent, London.

MEDICAL SECRETARY, Medisecra Westcent, London.

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumshugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

Wanted: Experience in Schick and Dick Testing

"A COUNTRY G.P." (Shropshire) writes: Can any of your readers tell me where I could get practical experience in carrying out the Schick and Dick tests for diphtheria and scarlet fever?

School for Backward Child

"N. A. M." asks if any reader can recommend a school, in the North for preference, for a girl 14 years of age whose mental outlook is that of a child half her age.

Oliguria

Dr. U. W. N. MILES writes: I have a patient with the following remarkable history, and I am wondering whether anyone can give me an explanation or any suggestions for treatment. The patient, a woman of 65, has been suffering for the past two months from acute melancholia, which has gradually improved lately. About three weeks ago (May 1st) she complained of pain on micturition. She was put on an alkaline mixture, and as she passed no urine in twenty-four hours she was catheterized. The amount withdrawn was only 4 oz. She passed practically no urine normally for several days after this, and on being catheterized only a maximum of 4 to 5 oz. was obtained in any twenty-four hours. She was put on diuretin 20 grains three times a day, but this had no effect. Now, three weeks after the onset of the suppression, she feels fairly well, has no symptoms of uraemia at all, but is still passing only 2 to 4 oz. daily. She has gone as long as forty-eight hours without passing any at all. I am completely puzzled to account for the absence of uraemic symptoms. Would somebody explain. I should add that a trained nurse is in charge, so that the facts are as stated.

Income Tax

Car no Longer Required

"L. C. D." bought a car in 1931 when he was an assistant. He left that engagement and did locumtenent work until he entered a partnership in 1933. The car was handed over to a garage for sale when his assistantship ceased in 1932, and he lost £47 on it. Can he claim any deduction?

** The only claim he can make is for depreciation allowance at 20 per cent. per annum on the cost of the car (£55) for the period up to the date when his assistantship ceased. No other claim is possible, because the use of the car was restricted to that work, and the £47 was a loss of capital.

Depreciation Allowance.

"H. E." has for many years claimed the cost of renewal of his car instead of depreciation plus obsolescence, but now wishes to make a change. His last transactions were: January 1st, 1931, bought a car for £298; January 1st, 1934, sold the car for £75 and bought another for £259.

** In making his return for assessment for the current year 1934-5, which will be based on the profits of 1933, "H. E." can claim a depreciation allowance based on the written-down value of the old car as at December 31st, 1933—that is, £190 at 20 per cent. = £38. The running costs, including repairs, will, of course, be charged as in previous years. When he makes his return up for 1935-6 on the basis of his 1934 profits, he can claim as an obsolescence allowance his out-of-pocket expenditure—that is, £269 - £75 = £194 less the £38 claimed—that is, £156 net as an expense and 20 per cent. on £269 as a depreciation allowance for 1935-6.

Expense of Additional Qualification

"T. W. B." has expended about £120 during the last three years in fees in connexion with additional medical degrees or other qualifications. Are these expenses deductible for income tax purposes?

** No. There is, unfortunately, no doubt but that these expenses are not legally allowable. They are not incurred... in the carrying out of the work of the practice, but in improving the status and professional knowledge of the practitioner, and consequently are in the nature of capital expenditure.

LETTERS, NOTES, ETC.

The Cause of Hyperpiesia

Dr. C. P. DONNISON (Cheltenham) writes: With reference to the points raised by Dr. G. Arbour Stephens (May 5th, p. 831) regarding my article, I wish to state that in matters of definition and technique I have, as stated in my previous article, been guided by Dr. Halls Dally in his book *High Blood Pressure*. The armlet of my sphygmomanometer was five inches in width. A blood pressure that was consistently above 160 mm. systolic or 100 mm. diastolic was regarded as hyperpiesia, whilst in young subjects a systolic pressure persistently above 150 mm. was included.

Open-Air Schools

The Open-Air Schools League of New Zealand, in a recent pamphlet, makes a plea for still greater recognition of the "opportunities afforded by open-air schooling." While it is admitted that the cost of education is mounting, it is held that the reforms which the League has at heart could be achieved with little or no expense. Playground classes could be instituted throughout the Dominion, and many old schools converted into semi-open-air schools at a cost which would be almost negligible. When these avenues had been explored, the pamphlet states—and new buildings were imperative—then inexpensive classrooms modelled on the Dominion's Fendalton open-air classroom should be erected.

Disclaimer

Mr. J. W. TUDOR THOMAS, M.S., F.R.C.S., writes from Cardiff: I write to disclaim all responsibility for the publicity given to my name in a professional capacity in the lay press. Recently my name appeared in a newspaper article in which the following statement appeared: "At first hand from the doctors and their patients themselves I have learned how all these astonishing operations are being performed." I have never discussed my professional work with representatives of the lay press, and have never conveyed information to them directly or by any indirect channels. Repeated requests for an interview have been made, which have been consistently refused, and I have an absolutely clear conscience on the matter.

A Correction

The discussion on the relationship of measles and whooping-cough to chronic inflammatory conditions of the chest was held by the Fever Group of the Society of Medical Officers of Health, and not, as stated in the *Journal* of May 19th (p. 916), by the society itself.

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 37, 38, 39, 40, 41, 44, and 45 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 42 and 43.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 268.

DIVERTICULITIS: A CLINICAL REVIEW

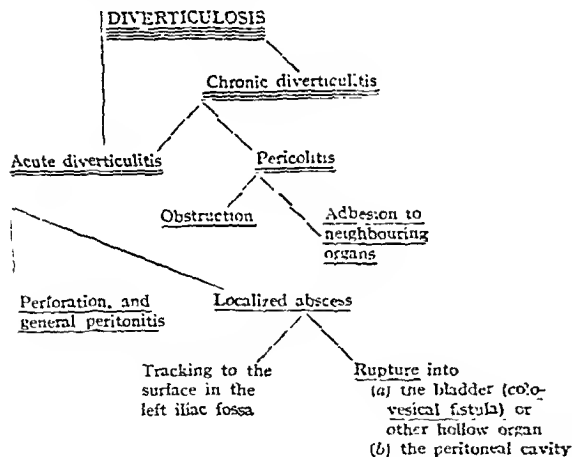

BY

HAROLD C. EDWARDS, M.S., F.R.C.S.

HUNTERIAN PROFESSOR AND JACKSONIAN ESSAYIST, ROYAL COLLEGE OF SURGEONS OF ENGLAND;
SURGEON TO KING'S COLLEGE HOSPITAL, LONDON

The circumstances of the anatomy and position of colonic diverticula predispose them to secondary pathological processes. They are bottle-necked, thin-walled sacs opening from a muscular tube, which contains faecal material rich in micro-organisms. The initiation of secondary changes depends entirely upon the retention of faecal matter within the diverticula, and it is clear that the more solid the stage which the faecal material has reached, the greater tendency there will be to retention. Hence the sigmoid colon is easily the commonest site for diverticulitis, not only because it is the commonest situation for the formation of diverticula, but because its contents are solid.

The presence of a faecal concretion may lead to a variety of secondary inflammatory changes, which are set out from the clinical standpoint in the accompanying scheme.

These changes vary from acute infection of the diverticulum, with perforation into the general peritoneal cavity, to a chronic reactionary fibrosis of the wall of the colon, extending in some cases to beyond the peritoneal covering. To such a condition the term "perisigmoiditis" is applied. Such a mass of inflammatory tissue may ultimately produce stenosis of the bowel simulating carcinoma, or cause adhesions between the colon and neighbouring organs.

Should acute diverticulitis supervene in a diverticulum walled off by fibrous tissue immediate perforation into the peritoneal cavity is improbable, and a localized abscess may form in the mass of fibrous tissue surrounding the colon. An abscess of large size may eventually rupture into a neighbouring hollow organ, such as the bladder, or into the peritoneum. Not infrequently an abscess of this kind will track along the side of the bowel to come to the surface under the parietes in the left iliac fossa.

The formation of intracolic and pericolic fibrous tissue may be due, in part, to the mechanical irritation of the faecal mass, but the main factor is probably infection from the lumen. This is due to the filtering of toxins or actual organisms through the damaged mucosa, which is stretched over the retained mass.

The Clinical Aspects

One hundred and forty-six cases, from various sources, of diverticula of the colon were investigated from the clinical standpoint. Of these, sixteen were cases of fistula into the bladder, the notes of which were loaned to me, and these will be excluded from the series for purposes of statistics. Of the remaining 130 cases, complications, due to the diverticula, occurred in nineteen, or 14.6 per cent. of the total. The complications were as follows:

	No. of Cases
Obstruction, large bowel	6
.. small bowel, from adhesions	1
Acute perforation	4
Abscess	3
Abscess with secondary perforation into the peritoneum	2
Fistula into the bladder	2
Fistula into the bladder and abscess in the pelvis	1
Total	19

This leaves 111 uncomplicated cases. In thirty-three of these other conditions were present, which were responsible for the symptoms either wholly or in part; thus seventy-eight cases of uncomplicated diverticulitis remain.

Uncomplicated Diverticulitis

Under this heading is included chronic diverticulitis with and without acute or subacute exacerbations, and this description is based on the seventy-eight cases in which neither complications nor associated abdominal disease were present. Though all these patients had diverticula of the colon, there was some difficulty in estimating the number who were suffering from diverticulitis as opposed to diverticulosis. Knowing that diverticula are present, by what criteria must one judge the presence of inflammation in them? In the more severe cases—those who are subject to acute or subacute exacerbations, or who have a palpable tender swelling—no doubt will exist, but in the greater number the symptoms are vague. While it is true that inflammation of mild degree may give rise to pain in the left iliac fossa, one must not lose sight of the fact that pain may arise from that disordered action of the bowel of which diverticula are the outcome.

The physical signs of thickening of the colon felt per abdomen must be accepted as evidence in favour of inflammation, but many of the patients are so obese that any such thickening cannot be felt. Mere tenderness over the colon is not an absolute sign, as it is frequently present in spastic constipation when x-ray examination

has proved the absence of diverticula. Involuntary spasm of the abdominal muscles is an absolute sign of subjacent inflammation, but if the colon is tender to palpation voluntary rigidity is also present, and may in some cases be very difficult to distinguish from reflex rigidity. X-ray examination may demonstrate spasm of the colon, but this may not be the result of inflammation in the diverticula; it may be the irregular action which is the prelude to their formation.

It will be conceded, therefore, that on the history, the physical examination, and the x-ray findings, it may be impossible to distinguish diverticulitis from diverticulosis, except in the severer cases, and I have failed in my attempt to estimate the percentage of cases of diverticulosis in which inflammation occurs. Rankin and Brown, in 1,300 cases in which diverticula were found in the colon, state that 17 per cent. were suffering from diverticulitis. If pain is regarded as a criterion of inflammation, then the following analysis of the symptoms will show that in the present series the percentage incidence is infinitely greater than this.

Analysis of Symptoms

In sixty-nine of the seventy-eight cases there were symptoms referable to the large intestine. The most constant of these was pain, which was present in fifty-four. This varied considerably in character; in some it was a dull ache, and in others it came in colicky attacks. Sometimes it was brought on by attempts at defaecation, but in others it was unaffected by this act. In forty-one of the fifty-four cases it was situated in the left iliac fossa. Other distributions were as follows: right iliac fossa, five cases; lower abdomen, four; umbilicus, one; and epigastrium, five, in two of which there was also pain in the left iliac fossa, and in the other three it was related to food. The site of the pain did not always correspond with the segment of the colon most affected by diverticulosis, as indicated by x-ray examination. In fifteen cases pain in the back was also complained of, but in the majority of these it may have been the result simply of constipation. There was no actual pain in fifteen cases, but the patients complained of disturbances of a more vague character, chiefly on the left side of the abdomen. These disturbances were variously described as rumbling noises, windy spasms, flatulence, soreness, and fullness of the stomach, and were felt more during defaecation, or when the patient was more than ordinarily constipated.

Constipation.—The bowel history was known in seventy-one of the seventy-eight cases. Only nine patients claimed to be normal in their bowel action. Forty-eight were constipated, and in thirty-three of these the constipation was of long standing and was severe. In thirteen it was of recent origin, and in two it was stated to be slight. There was a definite history of irregularity in six. The bowels were loose in three, and in five there was constipation alternating with diarrhoea; in three of these the bowel had previously been constipated. The latter condition must be regarded as significant of obstruction, but this is not always present, for the attacks of diarrhoea sometimes coincide with, and are due to, recurrent exacerbations of inflammation.

Blood and Mucus.—These were present together in three cases, and in three there was blood alone. Of these, one had severe cardiac disease and another had piles of moderate severity, but in the remainder no other cause for bleeding could be found. In a further series of twelve cases the test for occult blood was negative. Bleeding should not, therefore, be regarded as a characteristic of the condition. In the rare cases in which it is present it is probably due to associated colitis. Mucus was passed with stools in nine cases; this is a common accompaniment of severe constipation, however, and is not of special significance.

Bladder Symptoms.—Symptoms arising from the bladder were present in eight cases. Increased frequency and pain on micturition either together or alone were complained of on seven occasions, and in one case there was incontinence. It is difficult to say how far these urinary symptoms were directly due to the diverticula. In one case the patient

complained of frequency, pain, and a little difficulty. The urine was foul. The prostate was not enlarged, and the symptoms suggested that the formation of a fistula from the colon into the bladder was imminent. In two other cases the urinary symptoms were increased during attacks of abdominal pain.

Physical Signs.—Of sixty-four patients, thirty, or less than half, were obese. Of the remainder, twenty-five were regarded as of medium build, and nine as thin. In forty-four of the seventy-eight cases abdominal tenderness was present, in most instances in the left iliac fossa. This varied considerably in degree, from pain on deep palpation to severe pain on light palpation, with spasm of the overlying abdominal muscles. In twenty-four cases the sigmoid colon could be felt, and in five of these it appeared to be thickened. In eleven cases a definite lump was present, but in not all of these was the lump due to inflammatory thickening. In one patient, for example, a very large mass could be felt under the liver on the right side. It was diagnosed as a growth at first, but it disappeared with enemas, and subsequent x-ray examination showed diverticula in the distal part of the transverse and the sigmoid colon.

Clinical Diagnosis

Though the above analysis suggests that the clinical findings are for the most part vague, the diagnosis of diverticulitis is by no means a difficult one to make on clinical examination. The symptoms, taken in sequence as has been done above, do not furnish the true clinical picture, which is a characteristic one. Study of the case records shows the justification for this statement. A patient over the age of 45 complains of mild attacks of pain situated chiefly in the left iliac fossa. During the past few years he has noticed an increasing tendency to constipation. He feels a fullness on the left side, and puts his hand over the left iliac fossa and complains of tenderness there. The similarity to early malignant disease is patent, and one is not justified in accepting the clinical diagnosis of diverticulitis without excluding the possibility of growth—which not infrequently coexists—by x-ray examination.

Diverticula can occasionally be seen through the sigmoidoscope. In eleven examinations they were seen on two occasions. Sigmoidoscopy cannot be relied upon to any great extent for the diagnosis, however, which is far more readily made, and with less discomfort to the patient, by radiography.

Treatment of Uncomplicated Cases

The main treatment of uncomplicated cases of chronic diverticulitis is to avoid complications. Colonic lavage should be insisted upon, and every hospital which deals with this type of case should be equipped with facilities for this treatment in the out-patient department. The object is to wash away any retained products in the colon, and not to disinfect it, and it therefore matters little what lotion is used. Ordinary tapwater is probably as useful as any antiseptic solution, though one would not dispute the value of the natural waters at Bath and other spas.

The wash-out should be at body temperature, and the two details which must be insisted upon are: (1) not more than two pints should be used; and (2) the head of water should not exceed eighteen inches. This errs, perhaps, on the conservative side, but no one will deny the power for harm that lies in over-distension of the colon, especially the colon which has departed from the normal.

The diet should be mainly vegetarian; it need not be strictly so, but excess of cellulose should be avoided. The latter is an important item. The colon is not fitted to be a receptacle of the quantity of cellulose recommended by faddist societies, and to load the inflamed colon with undigested cellulose is clearly not to be desired.

Operative Treatment

The role of the surgeon in the treatment of diverticulitis is largely confined to the treatment of its complications. The nature of the disease and its irresistible tendency to adhesions make cases where local excision is possible very few and far between. In this series a radical operation was performed in five cases: there were three resections of gut, and in two the Mikulicz operation was performed. In only one case—a comparatively mild one—was the procedure limited to one operation. Though this patient remains in reasonable health to-day, six years after the operation, I regard the operation, in the light of additional experience, as unjustifiable, and a case of this low degree of diverticulitis I should now treat by medical means. The other four cases were progressing dangerously towards one of the complications, and it is only in such cases—one might almost say at this stage of the disease—that operation is justifiable. The difficulties that may be encountered, which make the decision to operate a weighty one, are well illustrated by one of my cases. The patient is now alive and well, but he underwent no fewer than five operations. The condition encountered at laparotomy did not justify an attempt to excise the mass, and hence the peritoneum on the left of the intestine was incised and the affected bowel mobilized and brought on to the surface of the abdomen.

Though the technique is difficult, when circumstances make it possible—that is, when the condition is localized—there is no doubt that the radical procedure in these borderline cases is the best line of treatment that can be offered. The alternative is an attempt to rest the diseased portion of the bowel by simple colostomy, with a promise to the patient that this will be closed at a later date. Such a method, however, not infrequently falls short of expectation.

Temporary colostomy—merely creating a fistula between the bowel and the abdomen—is doomed to failure. Such an operation only partially drains the bowel and does not allow of that degree of rest which is a *sine qua non* of recovery of the inflamed portion. The same applies with greater force to caecostomy, which is to be condemned except as a possible prelude to the radical operation. Apart from the distress it causes the patient, caecostomy gives only very imperfect drainage to the colon, and has a very limited effect upon the inflamed distal portion. This is clearly shown in one patient who suffered an acute recurrent attack of diverticulitis fourteen days after caecostomy had been performed as a preliminary to the radical operation.

It is essential, therefore, for the colostomy to be of permanent type if the patient is to derive any benefit. The question will arise, How long should the colostomy be allowed to remain? The question is unanswerable. There is no guarantee that symptoms will not recur after the colostomy has been closed by operation, even though all symptoms have subsided. A minimum period of at least twelve months must be insisted upon. The closure of a permanent colostomy is not unattended by risk to the patient, even if one of the ingenious extraperitoneal methods are used. And for such an operation, successfully achieved, to be followed at a later date by a recurrence of symptoms is a grave disappointment to both patient and surgeon. If such a recurrence is severe, and the danger of complication appears imminent, the only operation possible is a second colostomy, for the previous operation would in all probability make the task of excision a difficult one.

The following guiding lines for treatment are therefore submitted: (1) Uncomplicated mild diverticulitis—medical treatment. (2) Severe recurrent diverticulitis, in which complications appear to be imminent—laparotomy with a

view to determining the possibilities of excision, and if this be thought possible, a preliminary transverse colostomy or caecostomy. Operation should be postponed to an interval between the attacks. If the condition met with appears unsuited to radical treatment, a permanent type colostomy, made as near as possible to the inflamed area, and left open for a minimum period of twelve months.

Diverticulitis with Obstruction

Six cases of chronic fibrous obstruction of the large bowel due to diverticulitis appear in my series. The complication is therefore not uncommon. The similarity, both in history and in physical signs, and even on naked-eye examination, between this condition and carcinoma of the bowel is well and widely recognized. In one case the nature of the condition was only revealed by microscopical examination after the mass had been resected at operation, which was successfully performed in one stage. In a second case the patient had been admitted a year previously and treated by colon wash-outs. She was well on discharge, but neglected to continue with the treatment, and was readmitted with acute obstruction. A Mikulicz many-stage operation was satisfactorily performed. The sigmoid colon had become obstructed in a third case by a band passing from an inflamed diverticulum to the left Fallopian tube, while in a fourth a caecostomy had been performed, but, two years later, x-ray examination demonstrated that the condition of the colon had not improved sufficiently to warrant closure. In two further cases the patients, who were both over 70, refused operation.

The difficulty in distinguishing, both clinically and at operation, between obstruction due to diverticulitis and that due to growth makes it imperative to remove the mass, either by resection or by the Mikulicz method. Radiography cannot always be relied on to differentiate between them, although the method of dual exposure, devised by my colleague Dr. Graham Hodgson, may be of help in many cases. The presence of diverticula elsewhere in the colon is no criterion whatsoever that the mass is inflammatory, as diverticula and growth frequently coexist. (Six cases out of 130.)

Obstruction of the small intestine as a result of adhesions to a portion of the sigmoid affected by the diverticulitis is perhaps the most serious of the complications. It was accompanied in one case by chronic obstruction of the colon itself. The left iliac fossa was filled with a mass of fibrous tissue, to which a coil of the ileum had become firmly adherent. The ileum above the obstruction was dilated and its wall thickened. The surgical treatment here is a problem of considerable difficulty. It is manifestly useless to attempt to separate the adherent ileum from the colon, for recurrence is certain, and the obstruction must be short-circuited either by ileo-ileostomy or ileo-transverse-colostomy. In addition the obstruction to the colon must be treated. In the case in the present series the ileal obstruction was a chronic one situated about three feet from the ileocaecal valve. An ileo-ileostomy was made around the obstruction, and a transverse colostomy performed. The patient died three days later from ileus.

Acute Perforative Diverticulitis

This complication is, fortunately, rarer than might be expected. Diverticulitis is usually an insidious disease, and the diverticula are walled off by the formation of fibrous tissue. It occurred in four cases in the present series.

The history and pathological process are similar to that of perforation of the appendix into the general peritoneal

cavity, except, of course, that the early pain and the physical signs are on the left side of the body. There is usually a history of vague pain preceding the acute onset, but on occasion this is absent, the acute condition appearing with dramatic suddenness. Perforation may follow some strain, or occur during a prolonged attempt to defaecate. An important sign not obtained in perforation of the appendix is an early distension of the abdomen, with a tympanitic note on percussion due to the presence of gas.

It goes without saying that immediate operation should be performed in these cases. The conduct of the operation, once the abdomen is opened, will depend entirely upon whether the perforated diverticulum can be found or not. In one case this was possible. The diverticulum, which was at the upper end of the rectum, was excised, the opening in the bowel closed by a purse-string suture, and a temporary caecostomy used to relieve the distension of the large bowel. A drainage tube was placed down to the site of the opening into the bowel.

If the site of perforation cannot be determined, or the opening be buried in a mass of fibrous tissue so that it cannot be closed by any plastic operation upon the bowel, the great omentum is brought down and fixed over the area with one or two stitches, and a colostomy performed as close to the area of diverticulitis as possible, and the abdomen drained.

Though the prognosis of the former class of case is relatively good, that of the latter is poor. In the present series the one patient in the latter class personally operated upon succumbed.

Abscess with Diverticulitis

The formation of a localized abscess is a not uncommon sequel to diverticulitis. In the majority of cases its formation is accompanied by an attack of acute diverticulitis, with a high temperature, and, not infrequently, diarrhoea. The acute inflammatory condition may subside suddenly when the abscess ruptures into a neighbouring organ, such as the small intestine, rectum, vagina, or bladder. In three cases the abscess ruptured into the peritoneal cavity, and terminated fatally.

The appearance of a collection of pus under the abdominal wall may be accompanied by only the mildest symptoms, but a history of an acute attack of abdominal pain preceding the formation of the swelling is usual. The insidious manner in which the swelling appears may mislead one as to its true nature. In one such case a woman patient had a fluctuating swelling in the left iliac fossa, with no inflammatory signs, and only a small evening rise in temperature. The condition was regarded as tuberculous until investigation of the contents revealed its true nature.

From examination of one specimen, in which there is a small abscess cavity in the centre of the pericolic mass of fibrous tissue, it seems probable that a small abscess around a diverticulum buried in fibrous tissue may be absorbed, without having given any indication of its presence. Indeed, it is probable that such abscesses are frequently formed during an attack of acute diverticulitis.

If it is clear that an abscess associated with diverticulitis is present, it should be opened. Whether or not at the same time colostomy should be performed depends very much on the condition found. Generally speaking, a conservative policy, confined to dealing with the needs of the moment, is wisest. The abscess should be drained, and the inflammatory condition allowed to subside, before deciding upon the line of treatment to be adopted for the underlying diverticulitis. In one case so treated a small faecal fistula developed through the operation incision in the left iliac fossa. This persisted for four years, during

which time the patient was free from symptoms. At the end of this period, however, the fistula suddenly closed, and another peridiverticular abscess developed, which was opened, and a colostomy performed. The latter is still present, and the patient remains well.

Colo-vesical Fistula

Though rarely of itself a cause of death, colo-vesical fistula is one of the most dreaded complications that may follow upon inflammation of diverticula of the colon. Of nineteen cases of colo-vesical fistula due to diverticulitis sixteen were in men and only three in women. The oldest was 69 and the youngest 44; the average age at onset was 54. The characteristic symptom of the condition is the passage of air and faecal material per urethram. In all cases there was a history, varying from thirteen years to one month, of acute pain in the abdomen. The average duration, in fifteen cases, of abdominal symptoms before the onset of the passage of air and faeces was three years and nine months. In most of the cases the onset of urinary symptoms corresponded with an acute attack of abdominal pain accompanied by fever. On occasion urinary symptoms suddenly abate. Thus in one case pus suddenly appeared in the urine during an attack of acute pain, which had lasted for a few days, and on the appearance of the pus the pain rapidly subsided. This was unquestionably due to the rupture of a perisigmoid abscess into the bladder. It may take some little time before a fistulous track from the colon into the bladder is established in consequence of this rupture, so that the passage of air and faeces per urethram may not follow the first appearance of pyuria and the appearance of faeces in the urine was ten days; the latter followed a dose of castor oil taken to disperse the lump in the left iliac fossa. In another case the interval was two years, and in a third frequency of micturition heralded the onset of pneumaturia.

The quantity of both air and faeces passed once the fistula is established varies considerably. In some cases it appears only at intervals, and there is considerable improvement in between. In two cases faeces were passed, but the patient was never conscious of the passage of air. One of these was a man and one a woman. In a third case, in which this symptom was absent, a colostomy had been performed before the fistula developed.

The bladder nearly always becomes inflamed, especially in the early stages, and frequency of micturition both by day and by night is common. One of the most notable features, however, is the apparent immunity to infection by the faeces which the bladder ultimately develops. In these cases, except during the periods when faecal material is passed in considerable quantity, the urine is clear, and the patient relatively free from bladder symptoms. Cystoscopy reveals a healthy bladder mucosa.

Ascending infection from the bladder to the kidneys is of relatively rare occurrence, owing, presumably, to the acquired immunity of the bladder mucous membrane, and this customary freedom from attacks of pyelitis must be borne in mind when deciding upon the treatment to be carried out in each case. In this series only one patient suffered symptoms of pyelitis, and this was limited to one attack. Haematuria occurred in three cases; in one it preceded by a month the passage of air through the urethra. In one or two cases the patient has been troubled at intervals by the passage of large quantities of mucus per urethram. A phosphate stone

subsequently developed in the bladder in two of the cases, in one of which a colostomy had been performed previously to relieve the condition. The onset of symptoms due to the stone was six months after this operation.

The diagnosis of colo-vesical fistula is readily made from the clinical history. X-ray examination is of little assistance, except to exclude the possibility of a malignant fistula. The barium does not readily enter the fistulous track, and it is a matter for comment that in radiographs of some of the cases the bowel does not appear to be grossly affected by diverticulosis. The clinical diagnosis is confirmed by cystoscopy, which will reveal the opening into the bladder. In the majority of cases this is situated near the apex on the postero-superior wall to the left of the midline, though in one case the opening was to the right of the midline. In some cases the opening may be masked because of the oedema of the wall consequent upon infection, and owing to the ease with which faeces pass through the fistula it becomes difficult to obtain a clear medium in the bladder through which an adequate inspection can be made. In such cases a preliminary course of bladder lavage must be instituted, and an attempt must be made to keep the bowels constipated for a few days prior to the cystoscopic examination.

Treatment of Colo-vesical Fistula

The ease of diagnosis is but a poor compensation for the difficult problem which confronts one as to the wisest treatment to adopt for colo-vesical fistula. The histories of the nineteen cases were as follows: colostomy, three cases; radical operation, one; radical operation and colostomy, three; no operative treatment, twelve; colostomy advised but refused, five; and spontaneous healing, one.

Colostomy.—The results obtained in three patients indicate that the case for colostomy is not a strong one. In one patient a fistula formed a year after colostomy had been done for diverticulitis. One should not lose sight of the fact that a colostomy is not the most desirable thing for the patient to live with, and the patient should not be made to pay the price of a permanent colostomy without any guarantee of reward in the alleviation of the bladder symptoms. In five cases in which colostomy was suggested the patients, probably wisely, turned it down, preferring to put up with the inconvenience of a fistula into the bladder than of one on to the abdominal wall. It must be remembered also that the bladder frequently becomes tolerant to the infection, and attacks of pyelitis are rare. The diverticulitis abscess has ruptured, and is draining into the bladder, so that which colostomy aims to do by operation has been achieved naturally. Moreover, there seems to be just as much liability to the development of a secondary abscess with the bowel draining on to the abdominal wall as with the bowel draining into the bladder. In one case urine actually leaked through the lower colostomy wound when the patient passed water. On this evidence colostomy is not a sound line of treatment, and certainly should not be undertaken without the patient being fully alive (a) to the discomfort of a colostomy, and (b) to the absence of any guarantee of cure of the bladder symptoms.

Radical Operation.—In the one case in which the radical operation was performed in one stage the fistula recurred after four months. The one-stage operation is unsuited to the condition, and I do not now give it any place in the treatment; in my view it should be abandoned.

Radical Operation with Colostomy.—Of the three cases in which radical operation was combined with colostomy one patient has been lost sight of. In the successful case

a first attempt at closure failed. The essential difference between this and the second and successful attempt was that in the latter the suture lines in the bladder and colon were separated by interposing the omentum. Though all three patients survived their operations, reference to the literature shows that the operation carries a relatively high mortality. It is difficult of accomplishment, and the subjects are nearly all poor operative risks. Suitable cases in which operation is justifiable are therefore few and far between, and if doubt exists discretion will be the better part. So far the case for operation is not a strong one. Colostomy alone is disappointing, and the operation for closure is only justifiable in a small proportion of cases.

What is the result of non-operative treatment? One patient in this series apparently underwent a spontaneous cure. Ten of the remainder continued in fair health. Not one of them suffered the stormy incidents that figured in some of the operated cases. In nearly all of them the attacks of abdominal pain were less frequent and less severe after the fistula had formed than before. The colon had acquired a natural safety-valve. This, in conjunction with the high degree of bladder tolerance and freedom from pyelitis, already commented upon, allowed the patients to lead a comparatively happy existence. At least five of them preferred the fistula to a colostomy.

A great deal can be done to alleviate the bladder condition by frequent bladder wash-outs, either in a course or at regular weekly intervals. The technique is simple, and the patients have little difficulty in acquiring it themselves. Dilute antiseptics, such as 1 in 20,000 oxycyanide of mercury, should be employed.

Conclusions as to Treatment.—Owing to the extreme difficulty of operation, the lack of guarantee of success, the high mortality, and the poor operative risk, an attempt to close the fistula at operation should only be undertaken when the patient is comparatively young and the fistula of recent occurrence. The operation should be preceded by a preliminary colostomy.

I wish to thank the Council of the Royal College of Surgeons for permission to use material from the Jacksonian Prize Essay, 1932, in preparation of this review, and my medical and surgical colleagues at King's College Hospital for permission to utilize their cases. I also wish to thank Sir John Thomson-Walker for his very kind loan of the clinical notes of some of his cases of fistula into the bladder.

The fourth conference of the International Association of Preventive Paediatrics (medical section of the Save the Children International Union) will be held this year at Lyons on September 27th and 28th. The subjects to be discussed and the names of the rapporteurs are: (1) "The Prophylaxis of Malaria in Children," by Professors Cacace (Naples) and Gillot (Algiers), with whom will be associated Dr. Larrouy (a British rapporteur will be named later); (2) "The Prophylaxis of Rickets and Convulsions," by Professors Adam (Dantzig) and Monrad (Copenhagen). Those who desire to be present at the conference, as well as to take part in the discussions following on the reports, are requested to communicate with the secretary of the I.A.P.P., 15, Rue Lévrier, Geneva, Switzerland.

EPHEDRINE AND PSEUDO-EPHEDRINE IN ASTHMA, BRONCHIAL ASTHMA, AND ENURESIS*

BY

J. B. CHRISTOPHERSON, C.B.E., M.D., F.R.C.P.
F.R.C.S.CONSULTING PHYSICIAN TO THE CITY OF LONDON HOSPITAL FOR
DISEASES OF THE HEART AND LUNGS; PHYSICIAN (TROPICAL),
ROYAL MASONIC HOSPITAL, LONDON

AND

MARJORIE BROADBENT, M.R.C.S., L.R.C.P.
D.P.H.CLINICAL ASSISTANT, CITY OF LONDON HOSPITAL FOR DISEASES OF THE
HEART AND LUNGS

The work here described was part of an inquiry arranged by the Therapeutic Trials Committee into the relative values of ephedrine and pseudo-ephedrine. The ephedrine and pseudo-ephedrine hydrochloride used in the tests were supplied to the committee by Messrs. Burroughs Wellcome and Co., who also provided a quantity of inert tablets for use as controls.

The comparative pharmacology of ephedrine and pseudo-ephedrine is discussed in detail elsewhere in a paper by Dimson.¹ The two alkaloids occur together in varying proportions in the several species of *Ephedra* used commercially for the manufacture of ephedrine. They have the same chemical structure—namely, $C_6H_5.CHOH.CH(NH.CH_3).CH_3$. There is, however, a physical distinction between the two, ephedrine being laevorotatory and pseudo-ephedrine dextrorotatory. On the basis of the findings with regard to other optical isomers, such as *l*- and *d*-hyoscyamine, it might be expected that ephedrine and pseudo-ephedrine would have similar qualitative actions but would differ quantitatively. Clinical evidence may be said generally to support this view.

Before the trials were begun the actions of ephedrine and pseudo-ephedrine had been compared in India by Chopra, Krishna, and Ghose,² who reached the following main conclusions:

1. Both ephedrine and pseudo-ephedrine have a pressor action, the former being more powerful than the latter.
2. Pseudo-ephedrine is less toxic than ephedrine.
3. The dilator action of pseudo-ephedrine on the bronchioles is nearly as marked as that of ephedrine; and so is its constricting action on the mucous membrane of the nose. Both ephedrine and pseudo-ephedrine are useful in asthma, the latter having the advantage of producing fewer "side-effects."
4. Pseudo-ephedrine is more powerfully diuretic than ephedrine.

Apart from observations on a few ambulant cases of asthma, the blood pressures in which were subnormal, we have not explored the pressor action of these drugs. They have recently been carefully compared in patients by Dimson¹ and by Monro.³ The findings of these workers, and our own so far as they go, support the conclusions of other investigators that the pressor action of pseudo-ephedrine is much less than that of ephedrine.

Our inquiry has been directed mainly to the action of ephedrine and pseudo-ephedrine in asthma, in "chronic bronchitis," and in enuresis. In the course of this work we have naturally had an opportunity of comparing the toxicity of the two isomers, and of observing incidentally their supposed diuretic actions. It may be said at once, however, that, although we have not used pseudo-ephedrine intentionally as a diuretic where such was indicated, we have obtained no evidence in our inquiry

that it acts in this way in patients with normal cardiovascular systems. None of our patients has complained of increased frequency of micturition when taking it; in fact, the converse has, in a sense, been true, for pseudo-ephedrine has been used with success in the treatment of enuresis in children.

Comparative Tests in Spasmodic and in Bronchial Asthma

For the purposes of this study we have classified our asthmatic patients on the basis of symptoms and routine clinical examination into: (a) "spasmodic" cases—that is, cases without gross evidence of bronchitis, etc.; and (b) "bronchial" cases—that is, cases with gross evidence of bronchitis, etc.

SPASMODIC ASTHMA

Twenty-four cases of this type were treated successively with ephedrine and pseudo-ephedrine, with an interval between the two drugs, during which the patients were treated with inert tablets made to resemble those previously given. Ten of the patients were under the age of 10. Both ephedrine and pseudo-ephedrine were ordinarily given at bedtime in doses of 1/4 to 2 grains, according to the age of the patient and the reactions obtained: when necessary, however, the same dose was repeated in the morning on waking, or later in the day. The results may be summarized as follows: Five had no bad attacks during the whole period of observation. Fifteen were relieved of wheezing and dyspnoea both by ephedrine and by pseudo-ephedrine, but pseudo-ephedrine was less effective than ephedrine in relieving definite attacks. Four were relieved of wheezing and dyspnoea by taking pseudo-ephedrine every night. In these, pseudo-ephedrine was also effective in the attacks when they appeared, but less promptly than ephedrine in the same dosage.

BRONCHIAL ASTHMA*

The results in thirty-seven cases of this type were as follows. In eight, pseudo-ephedrine was not effective for acute attacks, though useful for chronic dyspnoea and wheezing. In nine, pseudo-ephedrine, in addition to its use in preventing attacks, was also effective in relieving slight attacks. Twenty patients had no severe attacks, and in fifteen of these pseudo-ephedrine, taken regularly, relieved nocturnal dyspnoea and wheezing.

It should be mentioned, incidentally, that thirty-two of our cases of spasmodic and bronchial asthma were also under treatment with sodium iodide throughout the inquiry. We have found this drug of definite value in the prophylaxis of asthmatic attacks. Our usual procedure is to give 30 grains at 6 p.m. and at bedtime. To more obstinate cases we also give 30 grains sodium iodide intravenously once a week. Complete immunity from severe attacks may be obtained for many months with this medication, but, in our experience, most patients need an additional safeguard in order to obtain freedom from nocturnal wheezing and dyspnoea. We have found both ephedrine and pseudo-ephedrine useful for this purpose, pseudo-ephedrine being frequently the more satisfactory on account of its lower toxicity. Of nineteen cases which gave a definite response to pseudo-ephedrine and were not under the influence of sodium iodide, twelve had relief from nocturnal dyspnoea when taking pseudo-ephedrine 1/2 grain regularly at bedtime; the remainder required 1 to 2 grains, according to the severity of their symptoms.

* In this group we have included, as stated, all the cases under observation in which asthmatic attacks were associated with gross evidence of chronic bronchitis. But, in the view of one of us (J. B. C., *Amer. Journ. Med. Sci.*, 1933, clxxxvi, 504), the disorder known as "chronic bronchitis" itself needs reviewing and reclassifying in relation to modern knowledge. For the accurate sorting out of the different conditions at present labelled "chronic bronchitis" on clinical grounds, a lipiodol examination of the lungs is necessary.

* A report to the Therapeutic Trials Committee of the Medical Research Council. One of the authors (J. B. C.) received a grant towards the expenses of this work from the Science Committee of the British Medical Association.

It may be said generally that pseudo-ephedrine is useful in any case of wheezing and dyspnoea due to spasmodic constriction in the bronchial tree. We have also found it of value in the chronic "exertion" dyspnoea associated with severe fibrosis of the lung, as in tubercle or bronchiectasis.

Toxic Effects of Ephedrine and Pseudo-Ephedrine Compared

Toxic reaction to ephedrine in small doses is more frequent than is perhaps generally realized. It leads many patients to delay taking the drug until the asthmatic attack actually appears—when ephedrine, compared with asthma, is regarded as the lesser of two evils. This reluctance to take ephedrine as a prophylactic is unfortunate, since experience shows that the greatest value of this drug is as a preventive. If, therefore, pseudo-ephedrine could be shown to be nearly as good as ephedrine in this respect, while being less toxic, it would have obvious clinical value in the routine treatment of asthma.

We found that the toxic symptoms produced by ephedrine and by pseudo-ephedrine were similar in nature, but differed in frequency of occurrence and in the dosage necessary to induce them. Thus in sixty-one asthmatic or bronchitic patients treated with both drugs thirty-two showed hypersensitivity to ephedrine, sixteen to pseudo-ephedrine, and thirteen to both. Of the thirty-two cases which showed hypersensitivity to ephedrine three had toxic symptoms with doses of 1/4 grain, twenty-three with 1/2 grain, and six with 1 grain. Of the sixteen cases which were hypersensitive to pseudo-ephedrine one had toxic symptoms with doses of 1/4 grain, eleven with 1/2 grain, and four with 1 grain.

Palpitation of the heart was the most frequent unpleasant reaction both with ephedrine and with pseudo-ephedrine. After that came insomnia or restlessness during sleep. Nausea or gastric pain was the most frequent unpleasant reaction in children under 14. Then came certain nervous symptoms: "queer head," giddiness, trembling, sweating, "cold and sleepy feeling," "cramp" in fingers, tingling feeling in skin.

In fifteen cases pseudo-ephedrine seemed to have had an equal physiological effect with ephedrine in the same dosage. Of these, seven showed slight toxic or unpleasant reactions, distributed as follows: four with ephedrine, three with both ephedrine and pseudo-ephedrine, none with pseudo-ephedrine only. The common dosage in these cases was: in ten cases, 1/2 grain, in five cases 1 grain. One of the fifteen had toxic symptoms at first after ephedrine, but after a course of pseudo-ephedrine toxic symptoms seemed to be less marked with ephedrine. In fourteen cases ephedrine was more effective than pseudo-ephedrine, but produced more unpleasant reactions. In these the doses of pseudo-ephedrine were double those of ephedrine, and one patient, a boy of 6, had slight toxic reaction (restless night) after pseudo-ephedrine 1/2 grain. There is no doubt that in order to get the same physiological effect pseudo-ephedrine must ordinarily be used in larger doses than ephedrine. As a general rule 1/2 grain is a usual dose of ephedrine for an adult, whereas 1 or 2 grains of pseudo-ephedrine has to be given to produce a corresponding physiological effect.

Four cases appeared to be resistant to pseudo-ephedrine though they responded well enough to ephedrine. In one of these pseudo-ephedrine produced unpleasant reactions. Forty-four cases of the total were definitely responsive to pseudo-ephedrine in doses of 1/2 to 2 grains, but only in fifteen could it be maintained that pseudo-ephedrine had an equal physiological effect to ephedrine, and seven of these had slight toxic symptoms with one or both drugs. In nine cases where pseudo-ephedrine was effective but less so than ephedrine no toxic or unpleasant reactions occurred with either drug.

Ephedrine and Pseudo-Ephedrine in Enuresis

We have recently treated cases of enuresis with ephedrine, either alone or in conjunction with an alkaline belladonna mixture, and have obtained very satisfactory results. Our attention was first called to this treatment by a letter in the *British Medical Journal* by L. E. Parkhurst.⁴ He gave ephedrine 1/2 grain at bedtime to children aged 10 to 12, and claimed that the treatment was "almost specific." In view of the response to pseudo-ephedrine in the majority of our cases of asthma it seemed of interest to determine whether this isomer was also effective in enuresis.

Our experiments with pseudo-ephedrine were carried out on children varying in age from 3 to 13, all of whom were attending a hospital out-patient department. Altogether twelve patients were treated during periods varying from one to four months. Of these cases eight were controlled by ephedrine 1/4 grain given at bedtime without other treatment, and four were more severe and needed ephedrine 1/2 grain at bedtime with an alkaline belladonna mixture by day. One of these four appeared to depend more upon the belladonna mixture than upon the ephedrine, though the giving of ephedrine 1/2 grain at bedtime seemed definitely to increase the power of control; the same applied when pseudo-ephedrine 1 grain was given at night.

Speaking generally, the substitution of pseudo-ephedrine for ephedrine in the same dosage slightly decreased the extent of control, maintaining it at a somewhat lower level. Thus in seven of the eight cases controlled by ephedrine 1/4 grain pseudo-ephedrine had to be given in doses of 1/2 grain to produce a satisfactory result. Only one of these responded to 1/4 grain of pseudo-ephedrine. Similarly, of the four cases on ephedrine 1/2 grain plus the alkaline belladonna mixture, two required 1 grain of pseudo-ephedrine plus the mixture; the other two kept well on 1/2 grain. One patient to whom no ephedrine had previously been given improved at once with pseudo-ephedrine 1/4 grain at night and responded completely to 1/2 grain. In three patients, who had incontinence by day as well as by night, an additional dose of ephedrine or pseudo-ephedrine was given in the morning with benefit. No symptoms suggesting intolerance were complained of by these patients or noticed by their parents after either drug. It appears, therefore, that effective doses may be given to children quite confidently, and pseudo-ephedrine may be considered a useful addition to the somewhat limited therapeutics of enuresis.

Conclusions

1. Pseudo-ephedrine is valuable as a gentle bronchial sympathetic stimulant sufficiently active to give relief in chronic cases of wheezing and dyspnoea.
2. It is a useful prophylactic against the nocturnal dyspnoea of asthma and against the dyspnoea of exertion in chronic bronchitis.
3. It does not effectively take the place of ephedrine, still less of adrenaline in acute attacks of asthma.
4. It is non-cumulative in its action, and produces fewer "side-effects" than ephedrine in the same or rather larger dosage.
5. Generally speaking, though not always, about double the dosage of pseudo-ephedrine is required to produce the equivalent physiological effect of a given dose of ephedrine.
6. In cases of enuresis in children pseudo-ephedrine is also useful, though perhaps not quite equal to ephedrine, which we consider to have high value in this condition.

A NOTE ON THE TREATMENT OF ACUTE INFECTIVE ARTHRITIS OF THE KNEE-JOINT

BY

T. B. MOUAT, M.D., M.Ch.Ed., F.R.C.S.

HONORARY SURGEON, THE ROYAL INFIRMARY, SHEFFIELD

When a case of acute infective arthritis of the knee-joint is progressing unfavourably, in spite of repeated aspirations of the joint fluid and immobilization of the limb with effective extension, arthrotomy is usually performed. Arthrotomy on the ordinary lines—by antero-lateral and postero-lateral incisions—frequently fails to arrest the spread of infection, and it then becomes necessary to sacrifice the limb to save the patient's life.

During the performance of amputation through the thigh for this condition many surgeons, and particularly

vened had not been arrested by the incisions which were made a week later through the capsule of the joint. At the necropsy little pus was found in the joint itself, but a huge abscess, which contained over a pint of stinking pus, was found to extend upwards from the subcrureus pouch, in front of the lower half of the femur, deep to the extensor muscles. I was impressed by the resemblance to the spread of pyogenic infections of the flexor sheath up the forearm, and resolved to try the effect of treatment on similar lines at the first opportunity, which curiously enough arose the same night, in the following case:

A. B., male, collier aged 59, admitted to the Royal Infirmary, December 25th, 1931. He had been struck on the front of the right knee by a sharp corner of a steel plate, ten days earlier. The small lacerated wound on the outer side and above the patella became infected, and three days before admission he developed an acute infection of the knee-joint with rigors, and became seriously ill. On admission, pus spurted from the sinus on movement of the limb and on pressure over the swollen joint. A moderate amount of pus

FIG. 1.

those who had experience of surgery during the war, must have been impressed by the frequency with which an abscess is found to have spread up the thigh, from the subcrureus pouch to the cellular plane in front of the femur, deep to the quadriceps extensor muscles. The resemblance to the spread up the forearm in pyogenic infections of the common flexor sheath is striking. Kanavel described this, and the method of treatment he introduced, by prompt and early drainage of the infected sheath and of the cellular plane deep to the flexor muscles by the lateral incisions he described, which effectively drain the cellular space lying in front of the pronator quadratus and interosseous membrane, has completely altered the prognosis of that serious lesion.

In acute infective arthritis of the knee-joint the deep extension of infection to the subcrureus pouch and thence to the cellular plane in front of the femur is comparable with the line of spread of infection in the forearm, and early treatment on similar lines is advocated: by early drainage of the subcrureus pouch through lateral incisions, the outer of which is continued freely upwards through the vastus externus down to the bone, to drain the cellular space above the subcrureus pouch in front of the lower third of the femur.

The opportunity of making a complete dissection of the limb occurred some three years ago, at a necropsy in which death was due to septicaemia following infection of the knee-joint through a small wound from the point of a pick. The involvement of the joint was not originally suspected, and the acute infective arthritis which super-

FIG. 2.

was evacuated when the joint capsule was opened by lateral incisions. The outer incision was prolonged up the thigh through the vastus externus down to the femur. Some ounces of pus escaped from the subcrureus pouch, and a large abscess cavity, which extended up the lower third of the thigh, in front of the femur, was opened by the free upward extension of the incision. The infected subcrureus pouch, and the large abscess which ran from it up the thigh, were drained with strips of dental rubber. The infection gradually subsided, and the patient left the Infirmary at the end of three months with a stiff knee-joint but a useful limb, and resumed light work three months later.

Since then similar treatment has been employed, with success, in the following cases:

C. D., female aged 3½, admitted to the Sheffield Royal Infirmary on July 25th, 1932, with a history of three days' illness. The right knee-joint and lower thigh were swollen, with some redness of the skin, fixation of the knee-joint, and great tenderness over the lower end of the femur. Temperature 103.5°; pulse 135. Radiograms showed no evidence of any focus of infection in the bone. Pus was found in the joint on aspiration (*Streptococcus haemolyticus*). The capsule of the joint was opened by lateral incisions below the patella, and drains inserted down to the capsule, by the resident surgical officer. The temperature and swelling persisted, and on August 11th the subcrureus pouch and an extension abscess up the thigh, in front of the femur, were freely opened by lateral incisions, and drained with strips of dental rubber. The temperature thereafter remained down and the general and local condition slowly improved. The ultimate result was excellent, and the photographs of the case show that the range of movement is practically normal (Figs. 1 and 2).

E. F., male aged 31, on December 5th, 1932, ran a narrow chisel into the left knee-joint just above the patella. He thought it was merely a flesh wound, and applied pink lint and a bandage. The knee became very painful and swollen during the night, and on the following day the local condition was worse and he had several rigors. On admission to the Royal Infirmary on December 7th, the joint was distended with the skin inflamed around the small punctured wound, with streaks of lymphangitis up the thigh. Pus was aspirated from the joint (*Streptococcus haemolyticus*), and ether, introduced through the needle, bubbled out through the punctured wound, which had penetrated the subcrureus pouch. The subcrureus pouch, which was distended with pus, was emptied and drained through lateral incisions, the outer of which was carried upwards down to the femur. The drains were removed on the third day, and the discharge from the incisions and the joint reaction gradually subsided. Immobilization with weight extension was continued for three weeks, and he left hospital at the end of six weeks. He attended the massage department for four months, and when discharged had regained 45 degrees of flexion movement at the joint.

G. H., female aged 55, admitted to the Royal Infirmary, March 6th, 1933, diabetic, developed acute infective arthritis of the left knee-joint following extensive cellulitis of the leg. Haemolytic streptococci and *B. coli* were grown on culture of

the pus aspirated from the joint. The joint infection slowly subsided after transverse drainage of the subcrureus pouch and of the cellular space under the quadriceps through upward extension of the lateral incision. The limb was slung with weight extension, but the ultimate result was complete ankylosis of the joint with a fairly useful limb.

In the treatment of punctured wounds about the knee, when there is doubt as to whether or not the joint cavity has been penetrated, 2 or 3 c.cm. of ether should immediately be injected into the joint. Where the wound has involved the joint, the ether blows out from the external orifice, and immediate excision of the whole wound tract is indicated. The reaction set up by the ether in the synovial membrane appears to stimulate its resistance to infection.

Immobilization with suspension of the limb and weight extension and, if need be, repeated aspirations of the joint exudate are carried out. Where, however, acute infective arthritis of the joint develops or is already established when the patient comes under observation, the further steps described in the above article, on the lines of the Kanavel treatment of infections spreading up the forearm from pyogenic infection of the common flexor sheath, are recommended.

RENAL GLYCOSURIA MISTAKEN FOR DIABETES MELLITUS

BY

R. D. LAWRENCE, M.D., F.R.C.P.

AND

R. A. McCANCE, M.D., Ph.D.

THE DIABETIC CLINIC, KING'S COLLEGE HOSPITAL

It is over thirty years since Klemperer first drew attention to a harmless form of glycosuria, now generally known as renal glycosuria, but our clinical experience shows that it is still a frequent cause of diagnostic error. In this condition glucose appears in the urine at normal blood sugar concentrations because the renal threshold is low (under 0.17 per cent.), and not because hyperglycaemia exceeds a normal threshold, as in diabetes. The latter is particularly liable to be confused with cases of renal glycosuria in which the leak point is very low (under 0.100 per cent.) and the sugar excretion consequently heavy. Other reasons, too, contribute to mistakes in diagnosis, and unpleasant impositions of unnecessary treatment, as the following cases show.

CASE I

Mr. B., aged 47, underwent a complete examination before going abroad on an aeroplane expedition, for which perfect fitness was essential. Sugar was found in the urine, and a blood sugar curve was carried out, with the following result:

Time	Blood Sugar	Urine Sugar
Fasting: 50 grams glucose	Per cent. 0.037	Per cent. nil
1 hour after	0.053	0.4
1½ hours after	0.077	nil
2½ hours after	0.071	0.5

The subject was so anxious to go abroad, and the response to glucose was so unusual, that the man was suspected of having taken a dose of insulin before the test was made. When we repeated the curve (see table below) its general features were confirmed, showing a combination of an extremely high carbohydrate tolerance with a very low renal threshold.

Time	Blood Sugar	Urine	
		Sugar	Ketones
Fasting: 50 grams glucose	Per cent. 0.095	Per cent. 0.3	0
25 minutes after	0.125	0.8	0
40 minutes after	0.065	1.1	0
1½ hours after	0.111	0.4	0
2 hours after	0.178	0.5	0

CASE II

Mr. O., aged 30. Sugar was found in the urine during a routine examination when the patient had pityriasis rosea. He was at once put on a strict diet of 9 lines—that was, 45 grams carbohydrate, 67 grams protein, and 135 grams fat—and, since the urine still contained sugar after six weeks, a blood sugar curve was performed, with the following results:

Time	Blood Sugar	Urine Sugar
Fasting: 51 grams glucose	Per cent. 0.116	
32 minutes after	0.175	+
64 minutes after	0.133	+
120 minutes after	0.143	-

No record of acetone in the urine was made, but the curve was held to be definitely diabetic, as hyperglycaemia persisted after two hours, and diet was again prescribed. When first seen by one of us, after four months of rigid diet, the blood sugar was normal at 0.099 per cent. two hours after breakfast, and slight glycosuria was present, which suggested a low threshold. Full diet was then prescribed, and one month later the following absolutely normal, though irregular, curve was obtained.

Time	Blood Sugar	Urine	
		Sugar	Acetone (Rothera)
Fasting: 50 grams glucose	Per cent. 0.115	Per cent. slight trace	very light trace
½ hour after	0.087	trace	slight trace
1 hour after	0.137	1.5	0
1½ hours after	0.077	slight trace	0

It is probable that the first slightly abnormal curve was the result of the previous carbohydrate starvation, which produces *per se* a diabetic-type of curve in a normal individual.

CASE III

Mrs. P. This woman had complained to her doctor of thirst and polyuria, and on examination large quantities of sugar were found, and a diet of about 100 grams carbohydrate a day was prescribed. After some weeks the thirst and polyuria improved, but the glycosuria persisted and a blood sugar curve was carried out.

Time	Blood Sugar	Urine	
		Sugar	Ketones
Fasting: 50 grams glucose ...	Per cent. 0.131	+	0
½ hour after ...	0.67	+	0
1 hour after ...	0.155	+	0
1½ hours after ...	0.06	+	0
2 hours after ...	0.037	+	0

This curve was taken to be abnormal on the strength of the fasting level. No reference was made to the renal glycosuria, but shortly afterwards the patient was referred to the diabetic clinic at King's College Hospital for treatment. When first seen her blood sugar was 0.1 per cent., and her urine contained about 2 per cent. of sugar. Full diet was prescribed, and a few days later a blood sugar curve was obtained (see below), which showed a response to glucose approaching the "lag storage" type, with an unusually low threshold. The patient was discharged on full diet, and has since been untroubled by symptoms.

Time	Blood Sugar	Urine	
		Sugar	Ketones
Fasting: 50 grams glucose ...	Per cent. 0.097	3	0
½ hour after ...	0.200	3	0
1 hour after ...	0.161	3	0
1½ hours after ...	0.089	3	0
2 hours after ...	0.036	2	0
2½ hours after ...	0.059	3	0

CASE IV

Miss C., aged 24, a nurse in a provincial hospital, was discovered, during a routine examination, to have sugar in her urine. The test was repeated and diet prescribed. Later a blood sugar curve was done:

Time	Blood Sugar	Urine Sugar	
		Per cent.	Per cent.
Fasting: 50 grams glucose ...	0.100	1.8	
1 hour after ...	0.200	4.0	
2 hours after ...	0.180	5.0	

Here again the renal element was neglected, and the curve was taken to be abnormal because the effect of a period of previous carbohydrate restriction was neglected (see Case II). Treatment for diabetes was recommended, and a month later insulin was felt to be necessary, as the glycosuria persisted. Small doses were given at first, but later—as the urine was never free from sugar—larger doses were thought to be necessary, and the girl was finally discharged on 20 units b.d. After a year of treatment, with continuous glycosuria and frequent overdoses of insulin, she was admitted to King's College Hospital for investigation. Her diet, which had been 55 grams carbohydrate a day, was raised to 100 grams, and 34 units of insulin in the morning and 24 units in the evening were prescribed. It was appreciated next day that a low renal threshold must be present, as a heavy glycosuria was found with low normal blood sugars. Insulin was discon-

tinued, and as a normal blood sugar level continued for three days a full diet was prescribed. (It is of interest that a strongly positive Rothera's test for ketone bodies was obtained on this patient for two or three days after insulin was omitted, but never at any other time.) After a week of full diet a blood sugar curve gave the following result.

Time	Blood Sugar	Urine	
		Sugar	Ketones
Fasting: 50 grams glucose ...	Per cent. 0.098	5.2	0
½ hour after ...	0.123	5.2	0
1 hour after ...	0.151	5.6	0
1½ hours after ...	0.142	6.4	0
2 hours after ...	0.142	7.9	0
2½ hours after ...	0.115	—	0

The patient was discharged on full diet and has remained perfectly well. Six months later the blood sugar curve never rose above 0.12 per cent.

CASE V

Male, aged 31. This patient is a perfect example of how renal glycosuria may be confused with diabetes. Towards the end of a very hot summer he complained of lassitude, slight loss of weight, thirst, and irritation of the penis. His country practitioner found over 5 per cent. of sugar in the urine. Treatment for diabetes was commenced without a blood sugar estimation. Starvation did not remove the glycosuria, and the patient was referred to one of us as a severe diabetic for insulin treatment. The urine was found to contain 3 per cent. of glucose and a high excretion of ketone bodies (strongly positive FeCl test), but the first blood sugar estimation gave a low normal figure of 0.082 per cent., and at this figure 2.5 per cent. of glucose was excreted. After two days' very full diet the following blood and urinary figures were obtained after 50 grams of glucose.

Time	Blood Sugar	Urine	
		Sugar	Ketones
Fasting: 50 grams glucose ...	Per cent. 0.085	2.5	
½ hour after ...	0.161	9.8	No ketonuria
1 hour after ...	0.166		
1½ hours after ...	0.150	7.1	
2 hours after ...	0.093		

The slight delay in the return to the fasting level, caused presumably by recent ketosis from dieting, was neglected in view of the otherwise normal curve. Full diet was prescribed, and perfect health has been maintained for five years, in spite of heavy and permanent glycosuria. The previous slight irritation of the penis has been prevented by frequent cleansing.

Discussion

Little discussion is necessary. All five cases illustrate very well the difficulties that may arise if the possibility of a low leak point is not considered in every case of glycosuria without typical symptoms of diabetes. Cases II and IV show the advisability of prescribing full diet for some days before a diagnostic blood sugar curve is done, and Cases III and V the dangers of treating diabetics without adequate blood sugar control. Even without blood sugars, suspicion should have been aroused in these cases, for glycosuria without symptoms and without acetonuria in a young adult is always suggestive of renal glycosuria, and is seldom found in diabetes mellitus.

Summary

Five cases of renal glycosuria are described which, for various reasons, had been diagnosed as diabetes mellitus.

A CASE OF ACUTE BILATERAL MASTOIDITIS

BY

HERBERT V. O'SHEA, M.D., M.Ch., D.L.O.

ASSISTANT SURGEON, METROPOLITAN EAR, NOSE, AND THROAT HOSPITAL;
SENIOR SURGEON TO THE INVALID CHILDREN'S HOSPITAL,
PLAISTOW; ASSISTANT AURIST TO THE LONDON
COUNTY COUNCIL

The following case of bilateral acute mastoiditis, complicating acute fronto-maxillary sinusitis due to the *Streptococcus haemolyticus*, is, I think, worthy of publication because recovery ensued in spite of the fact that, in addition to the above complications, the infection spread to the base of the left lung and the wrist-joint of the same side.

Case Report

A married woman when eight months pregnant developed an ordinary cold. Being a strong, healthy person she gave little attention to this, which was considered a trivial matter; nevertheless it left her with an irritable cough and a certain stuffiness of the nose. Three weeks later a septic spot developed on her chin; this was eventually opened and had entirely healed before labour set in. The latter was quite normal, and in due course the patient left the nursing home.

Almost from the beginning the patient complained of face-ache on the left side; this grew worse and gradually spread until the entire left half of the face became very tender and could not bear pressure. The temperature began to rise at night, and the cough became more troublesome. On January 16th, 1934, three weeks after the confinement, I was asked to see the patient.

EXAMINATION

Pus was coming from the left frontal and maxillary sinuses. The middle and inferior turbinal bones on the same side were swollen and inflamed. Acute inflammation of both sinuses was diagnosed, and an exploratory puncture of the left maxillary antrum was made under nitrous oxide anaesthesia. I found the sinus full of thick, foul-smelling pus. I ordered menthol inhalations and hot fomentations for the frontal condition, and when I saw the patient two days later the pain and tenderness had considerably decreased. I again washed out the antrum, which now contained thin, watery, blood-stained pus.

OPERATION ON RIGHT EAR

The patient complained of earache on the opposite side—namely, the right. Inspection of the drum showed attic suppuration. The membrane was inflamed and bulging in the upper part, while it was more or less normal in the lower. Paracentesis was performed, and the patient was removed to a nursing home, as there was marked tenderness over the mastoid tip and I anticipated an extension of the disease into the bone itself. This proved to be correct, for the next morning the skin behind the ear was red and oedematous and exquisitely tender.

A conservative mastoid operation was performed. The bone was very thick, and contained abnormally large cells full of pus. I found it necessary to expose a large portion of the dura, the lateral sinus from well behind the genu, and the bulb. The posterior wall of the external auditory canal was removed down to the bridge, leaving the latter structure. The post-aural incision was closed, and the cavity drained through the meatus. At the same time I did an endonasal antrotomy. Some of the pus from both cavities was collected and sent for a pathological examination.

The following day, January 22nd, the condition of the right ear had considerably improved, but I was informed that the patient had had no sleep owing to the pain which had suddenly developed during the night in the left ear. This necessitated a hypodermic injection of morphine. Examination of the ear revealed acute attic suppuration. The appearances were exactly similar to those seen in the first instance, when the disease started in the right ear.

It was then that I received the following report from the pathologist.

EXAMINATION OF PUS FROM ANTRUM

The specimen was much admixed with blood, but direct films showed the presence of some pus cells (polymorphs) in addition to the blood cells, and a number of Gram-positive micrococci, mostly in pairs, but some of them in chains, were also to be seen. Pure growths of haemolytic streptococci of the *pyogenes* type have developed.

Opinion.—A heavy infection with haemolytic streptococci of the *pyogenes* type is present.

MASTOIDECTOMY ON LEFT EAR

This report, together with the rapid spread of the disease to the other ear, indicated the seriousness of the case. I performed a paracentesis on the left side that afternoon. Pus mixed with gas escaped under pressure, and the hissing noise made by the latter as it came away could be heard by those around. A large dose of anti-streptococcal serum was given at the same time. This was repeated on the following evening, and a third dose was administered three days later.

On January 23rd the patient's condition was worse. There was marked tenderness over the left mastoid, and on the following day I performed a mastoidectomy on the left ear. The condition found was similar to that on the right side, but much more advanced. The mucous lining of the mastoid cells had assumed a polypoid appearance, and as each cavity was opened the diseased membrane shot out like peas from a pod. The tegmen was entirely eaten through, and watery pus bathed the dura. It was necessary to expose a considerable area of the meninges to rule out an extradural abscess. The lateral sinus and bulb were also laid bare. In this case the radical operation had to be performed as the structures in the tympanic cavity were destroyed. The post-aural incision was closed and the ear drained through the meatus.

Immediately after the first operation it was noticed that the cough seemed to get worse. The sputum was blood-stained and contained pus. The report from the pathologist showed that the same organism, the haemolytic streptococcus, was present. Examination of the chest disclosed that the base of the left lung was affected, but the disease tended to be localized. This cleared up in about a fortnight, and the patient appeared to be none the worse for it. When I saw her in the first instance the left wrist was very inflamed, painful, and swollen. There was complete loss of power in it, and the forearm had to be kept in a sling. After the antrum was opened and drained this subsided. It is now quite normal, except for a little shooting pain at times.

Convalescence was uneventful and recovery rapid. The maxillary antrum was the only thing that caused any inconvenience. A viscid blood-stained discharge continued in spite of repeated washings and instillations of various antiseptics. I had this examined again, and it was found to contain the haemolytic streptococcus. It was, only after an autogenous vaccine had been made from the discharge and a course of injections given that the antrum cleared up. The patient now enjoys perfect health, and with the exception of a slight diminution of hearing on the left side, on which the radical operation was performed, she suffered no inconvenience whatever.

A blood count was twice made. The first, immediately after the second operation, was as follows: red cells, 2,700,000 per c.mm.; leucocytes, 10,160 per c.mm., of which 80 per cent. were polymorphs; haemoglobin, 46 per cent. The second, taken ten days later, showed: red cells, 3,720,000 per c.mm.; leucocytes, 8,040 per c.mm., of which 70 per cent. were polymorphs; haemoglobin, 65 per cent.

The anaesthetic given in the first operation was evipan sodium by intravenous injection, and in the second nitrous oxide and oxygen. Dr. M. Hudson administered the anaesthetic on both occasions.

I wish to thank Dr. John Oliver for his reports on the pathology of the case, and also Dr. Saxby Willis and Mr. Buckland Jones for their advice.

THE RADIOLOGY OF LIVING ANATOMY*

BY

JAMES F. BRAILSFORD, M.D.

RADIOLOGICAL DEMONSTRATOR IN LIVING ANATOMY, UNIVERSITY
OF BIRMINGHAM; HONORARY RADIOLOGIST, THE QUEEN'S
HOSPITAL AND THE ROYAL CRIPPLES HOSPITALS,
BIRMINGHAM

Sir George Newman's speech at the opening of the Annual Congress of the British Institute of Radiology in 1932 contained the following statement:

"When I was trained as a medical student, a great many years ago, I had to learn my anatomy on the dead body. But we may now, by means of *x* rays, learn in the ideal way (which we thought of in those far-off days as impossible to reach) of the anatomy of the living body; ideal, because all the tissues of the human frame are different in the dead body from what they are in the living. The *x* ray has, therefore, real weight in the study of human anatomy, of anatomy, not as it lies in dust and ashes, but as a living entity, the crown and summit of nature, the greatest thing as far as we know that has been created, on this planet at all events, if not in the whole universe."

Radiological study of the living body has contributed considerably to our knowledge of anatomy, but such knowledge must be regarded as supplementary to that which can be obtained in the dissecting room only. It is dependent on the relative density of the tissues or organs and their contents to *x* rays, and is in fact a study of shadows. While in the case of radiographs of the bones or of the lungs detail of the delicate structure can be portrayed, in most cases we have to base our knowledge on the internal or external contour of the organ. By the aid of substances of a lesser or greater density than the surrounding tissues we are able to show the outline of the interior of every tubular viscus. Finally, by the aid of the fluorescent screen, the movements of the viscera and skeleton can be followed.

Since radiology is now recognized as an essential method of examination, the extent and usefulness of which increases with improved technique each week, it becomes imperative for the medical student to appreciate the radiographic appearance of the normal anatomy. Unless the student or clinician has made himself familiar with the radiographic appearances, no matter how intimate his knowledge of dissecting room or surgical anatomy may be, he will be liable seriously to misinterpret the shadows produced by *x* rays. It is not suggested that the student should have an extensive course in radiology added to the already crammed curriculum. That it would have to be an extensive course if the whole subject were taught becomes obvious when we see how radiology has spread its tentacles into every branch of clinical medicine. So vast is the data already collected, and so rapidly are further advances being made, that it is certain radiologists of the future will have to specialize in the study of one system only if progress is to continue.

Radiology of the living anatomy may be learnt from: (1) radiographs taken in standard positions of patients of known age and sex; (2) serial radiographs taken at intervals of fractions of a second, minutes, days, weeks, or months to show development; (3) fluoroscopic examination; (4) cine-radiography. The student must first confine himself to a study of radiographs of normal structures at different age periods from infancy to old age, taken in standard positions. The variations to be seen in these, of the skeletal system alone, will indicate the extent of the knowledge required for correct interpretation. In no part are the variations of form more apparent than in the skull, in which we never see the

same radiographic appearance in two individuals, a factor which would be infallible for criminal records.

Obviously it will be impossible to give a very extensive account of the variations met with, and I shall confine myself to a demonstration of a few of the radiographic appearances of normal structures which have led to serious misinterpretation.

Radiography of the Skull

Radiographs of the skull must be taken with the central ray in the sagittal plane; the slightest obliquity of the skull respective to the central ray may result in the production of a radiograph in which the dense structure of the base obscures the normal accessory sinuses on one side, and this may lead to the error of diagnosing that the sinus is occluded. The dense shadow of the petrous portion of the temporal bone may be projected through the plane of the antrum, and its straight upper surface may be misinterpreted as a fluid level. The most serious results have followed the misinterpretation of shadows of pathological processes of the maxilla and mandible as the normal maxillary antrum or foramina. Examples have been published of septic foci which have been so missed in spite of repeated *x*-ray examinations, and in some instances the health of the patients has been seriously affected.

An unusual instance of misinterpretation of the normal was submitted to me three years ago. A child with a swelling at the angle of the mandible was *x*-rayed, and the radiograph was misinterpreted as showing a sarcoma. A surgeon was consulted, and resection of the involved bone was decided upon. Immediately before the operation the surgeon asked me if I could give him an indication of the boundary of the tumour, so that he could gauge what length of bone he must remove from the crest of the ilium to form a graft. It was demonstrated to him that the radiograph showed normal structures only; the shadow of the hyoid bone, which was projected against the mandible, had been taken for that of a sarcoma. It was discovered a few days later that the swelling was due to mumps.

When I was recently confronted by a dental surgeon's misinterpretation of the shadow of the pharynx as an abscess cavity with a sinus (the shadow due to the epiglottis) tracking forwards, I realized how necessary it was for the individual using *x* rays to learn the radiological anatomy of the normal before attempting to interpret pathology.

The Thorax

When radiographs of the thorax in inspiration and expiration are carefully compared it becomes apparent at once that radiographs must always be made in the same phase of respiration if they are to be compared one with the other. Radiographs of the thorax also indicate another important feature—namely, that those structures which are in close contact with the radiographic film appear denser than the surrounding tissues (owing to the fact that this area is, in this way, screened from secondary radiation), and often show a fairly well defined periphery. The significance of this fact is illustrated in the following case.

A patient was radiographed at a tuberculosis clinic, and a diagnosis of bilateral spontaneous pneumothorax was made. Later, when my opinion was sought, I suggested that further radiographs should be taken: one with reduced pressure against the breasts, and another with the film barely touching the patient. These proved that the abnormal shadows were due to the contact cutting out secondary radiations and consequently reducing the density of the protected part.

Contact of the male genital organs with the film results in the appearance of well-defined opacities on the radiograph, and these shadows have been misinterpreted as stones. Irregular calcification in the thyroid,

* Abstract of paper read to the Rugby and District Medical Society, and illustrated throughout by lantern slides.

cricoid, and costal cartilages also results in the appearance of opacities on the radiograph, which have been misinterpreted as evidence of tuberculosis, or, in the case of the lower costal cartilages, of stones in the gall-bladder or kidney. It is not unusual to hear that the normal appearance of the acromio-clavicular joint has been misinterpreted as showing a fracture. The importance of adopting standard positions in which the whole of the structure can be projected on the radiograph is illustrated by radiographs of the wrist or hip-joint, in which severe fractures may be masked by the overlapping of shadows of other structures.

Alimentary Canal

Little can be learnt of the anatomy of the alimentary canal by the plain radiograph. The lumen of the structures must be filled with some media, the density of which is less or more than that of the surrounding structures. It is the common practice to use a dense medium, such as barium. It is essential, however, before an opaque medium is introduced into any part of the body that a preliminary radiographic examination should be made, so as to be quite sure that no abnormal shadows exist which might be completely obscured by the opaque material. The essential part of the examination of the alimentary canal involves fluoroscopy, of which a brief account is given later. The gall-bladder can be visualized by absorption or injection into the portal circulation of such substances as sodium tetraiodophenolphthalein, which, being excreted by the liver in the bile, make the latter denser than the surrounding structures, it can therefore be shown on the radiograph. In this examination we are dependent in some cases on so-called negative shadows—that is, gall-stones less in density than the dye-containing bile. Such negative shadows may be simulated by the shadows of bubbles of gas in the duodenum being projected into the gall-bladder shadow.

Serial Radiographs

A single radiographic examination may, in health or disease, demonstrate clearly the outline of the structures under observation, but more information of the structures can be obtained by taking a series of radiographs with an interval of time (depending upon the nature of the examination) between each. If we are studying the movements of the heart, stomach, or small intestine, the interval between each radiograph must be very short, but if we are concerned with the development of the skeleton an interval of a month would suffice. The influence of sex, food, medications, ill-health, and endocrine disorders in the growth of the skeleton can be determined in this way. In the study of pathology this method of examination is invaluable, and provides evidence which cannot otherwise be obtained. Too often further radiography is neglected if the first examination has not revealed any abnormality.

Fluoroscopic Examination

When the student has made himself familiar with the radiographic appearance of the normal anatomy he will be in a position to appreciate the more quickly the shadows projected on the fluorescent screen. The time allowed for screen examination is necessarily limited, owing to the danger of exposure of the operator and patient to the x rays. The interest shown by students in the screen examination of their colleagues is sufficient testimony of the value of this method for bringing further stimulation to the study of anatomy.

Many of the features learnt from a study of radiographs will be readily noted by the student during the screening, but it is the observation of movement of the viscera and their contents which excites the greatest interest. Such

examinations teach the student the position of the viscera in the erect, supine, or prone position. The movements of opaque meals through the alimentary canal produce a living picture, which is of the greatest contrast to that exhibited in the dissecting room, and cannot fail to impress him.

Cine-radiography

The very limited time permissible during screening, and the limited area which the observer can watch, make this method of demonstration by no means ideal for teaching purposes. What we need is a carefully edited cine-radiographic film study of the viscera, an ideal which we are rapidly approaching. The desirability of this method of demonstration was recognized by Dr. John MacIntyre of Glasgow as early as 1896—that is, a few months after Röntgen had discovered x rays. He exhibited a cine-radiograph film 40 feet in length, showing the movements of the bones of a frog's leg, to a meeting of the Glasgow Philosophical Society in that year. In the *Archives of Skiagraphy* of April, 1897, he described his experiments with direct and indirect cine-radiography. This pioneer work has been followed up by other workers in different countries.

In this country Dr. Russell Reynolds contributed a paper in 1925 describing his experiments with indirect cine-radiography. (Since writing this Dr. Russell Reynolds has informed me that he has continued his experiments and now has a reliable technique which is relatively inexpensive.) More recently Robert Janker at Bonn advanced the method to such an extent that we reasonably expect soon to use cine-radiography in teaching the radiology of living anatomy. Briefly the two methods are as follows.

Direct Cine-radiography.—The patient is placed in front of an x-ray tube and against a leaded screen containing a window opposite the area to be radiographed. Behind the screen a large roll film of the necessary size is fixed on rollers, and the timing of exposure so devised that at least sixteen exposures per second can be made on the rapidly changing film surface. From the film obtained reduced films, capable of fitting into a cine-projector, would have to be made. The large contact films permit one to study the changes in form perhaps rather better than the small films obtained in the indirect method, but the cost is very considerable, and while the method may be used for the production of standard teaching films it can never come into general use in radiographic examination. Simpler devices have been made which enable us to take a dozen or more exposures within a short time, and these are useful in the examination of the stomach and duodenum. A modification of this direct method for recording the movements of the heart was described by Robert Knox in 1925.

The Indirect Method.—This method depends on a cine-photographic record of the images produced on the fluorescent screen. The screen image must be sharply defined, and there must be no afterglow. By this method Janker has been able to make cine-radiographic films which are little inferior to those obtained by the direct method but at a trifle of the cost. The intervals between each exposure will determine the rapidity (when shown in the cine-projector) of the movements of the structures examined. We may compare the cine-photography of growing flowers—in which there may be an interval of several hours or days between each exposure, but when projected the growth, which has taken several weeks and which was imperceptible to the eye, is completed in a few minutes—with the cine-photography of the horse-race during which many exposures per second are made, but when projected at the normal film rate appear as a slow-motion picture in which even the muscular contractions can be followed.

Both these methods may be applied to cine-radiography of the human body, and should solve many of the problems of visceral movement. The movements of the heart in diastole and systole during expiration and inspiration could be so analysed. The peristalsis of the alimentary canal could be determined with greater accuracy and films obtained which would be preferable to fluoroscopic screen demonstration for the teaching of students. By this means the movements of joints can be studied better than in any other way. Two years ago Professor Lockhart, Fowler, and I conspired together to show the movements of the spine. Our efforts are to be seen in Film No. 238 of the Kodak Medical Film Library. We determined, in this manner, that extension of the spine is greater than flexion, and that the greatest range of movement takes place in the lumbar area, the least in the dorsal. This was demonstrated in a girl who was able to bend backwards and place her head between her thighs. The extraordinary mobility of the lumbo-sacral joint was also demonstrated. In a woman, aged 34, I showed that, while with flexion of the spine the anterior surface of the sacrum formed an angle of 170 degrees, with the line of the anterior surface of the lumbar vertebrae with extension the angle had been diminished to 100 degrees.

Clinical Memoranda

TREATMENT OF PANCREATIC CYSTS

I recently published¹ an account of a case in which, in a male patient, I successfully anastomosed a persisting sinus, following external drainage of a pancreatic cyst, with the anterior surface of the stomach. This operation was rendered necessary on account of the excoriation of the skin of the anterior abdominal wall by the active pancreatic fluid discharging from the sinus. The result was so satisfactory that when I encountered my next case I decided to make an anastomosis between the cyst and the stomach at the first operation, and so save the patient several weeks or even months of discomfort resulting from that constant discharge of irritating fluid over the abdominal wall which invariably follows external drainage. The result exceeded my expectations. The abdominal incision healed by first intention, and the patient left hospital in three weeks. She has been seen several times since, and on October 30th, 1933, she was examined clinically and by radiography, but no sign of the cyst could be made out.

A woman, aged 50, was admitted into the Cardiff Royal Infirmary with a history of intermittent attacks of indigestion for four to five years. On July 11th, 1933, she had sudden severe pain in the upper abdomen lasting from two to three days. Examination revealed a large tense swelling in the upper abdomen, with the stomach and transverse colon running across its anterior surface.

The abdomen was opened through a right paramedian incision, and the cyst exposed by a two-inch incision in the gastrocolic omentum. An incision half an inch long was made in the cyst, and a catheter quickly introduced and secured by a purse-string suture previously inserted. The cyst was emptied and repeatedly washed with saline, through the catheter. The fluid first drained from the cyst contained altered blood from a recent haemorrhage, and this may have accounted for the severe attack of pain on July 11th. The catheter was then removed and the anastomosis made between the cyst and the anterior surface of the stomach near the greater curvature. A clamp was used on the stomach, but not on the cyst. The actual operation was performed in the same way as a gastro-enterostomy. To avoid the possibility of obliterating the opening during the suturing two devices were employed: (1) the sutures were

interrupted in three or four places; and (2) a piece of rubber tubing one inch long and a quarter of an inch in diameter was inserted into the two openings, after putting in the posterior halves of the sutures. When the sutures were completed the tube was pushed into the stomach. The abdomen was closed without drainage.

As the posterior surface of the stomach is adherent either to a true or to a pseudo-cyst of the pancreas, it might be suggested that it would be easier to make an opening in the stomach anteriorly, and then to make a stab opening through the adherent walls of the stomach and cyst. The same procedure might be carried out in the opposite direction after opening the cyst. There are, however, at least two theoretical objections to these modifications of the operation actually performed: (1) the stomach contents might enter the cyst and possibly give rise to complications; and (2) they resemble a perforation of the gastric ulcer into the lesser sac too closely to be undertaken without serious consideration, in view of the apparent safety of an anterior anastomosis.

I am indebted to Dr. Owen Rhys, radiologist to the Royal Infirmary, for the taking of the radiographs.

D. J. HARRIES, M.D., D.Sc., F.R.C.S.,
Surgeon, Cardiff Royal Infirmary.

INJURY TO THE CERVICAL REGION

The following case of injury to the cervical region presents some unusual features.

A man aged 24 was brought into hospital at 11.45 p.m. on August 30th, 1933, having been run into by a motor cyclist about half an hour earlier while helping to mend a puncture, his own machine lying close by. He landed with the three machines on top of him. There was no loss of consciousness, and the only apparent injury was a compound fracture of the right tibia and fibula, and some bruising of the left arm. The actual wound was half an inch long, and was bleeding freely; this was dressed, and the patient was put to bed with his leg on a back splint. The following day his general condition was good, but his temperature was 101.6° F. He said he felt well. He had no headache, his pupils were equal and reacted briskly to light, the tendon reflexes of his arms were present and equal, and those of his left leg were normal. The condition of his leg was quite satisfactory, and a stitch was put in the wound.

On September 1st, having slept well, he ate a good breakfast and appeared quite fit, except that his temperature was 100.4°. At about 10.30 a.m. he became strange in his manner. He answered questions as though not quite sure of what was being said, and he was found sitting in bed hanging his sound leg over the side. His expression appeared vacant. He said he had no pain or headache. His face was very flushed; his pupils were equal and reacted briskly to light, but were moderately dilated. By 12 noon he was only semi-conscious, and was incontinent of urine; by 2 p.m., thirty-nine hours after the accident, he was quite unconscious, lying on his back with his arms flexed across his chest. At 7 p.m. a crop of petechial haemorrhages was first noticed, symmetrically distributed on both shoulders, from first below the clavicle in front to the spine of the scapula behind, just encroaching on the upper arm; there was also a superficial haematoma spreading up the back of the neck to the occiput. The patient was sweating profusely on his face and neck; his temperature was 100.8°, his respirations stertorous and increased to 30, and his pulse 120, with volume and tension good. He was incontinent of urine, his bladder not being distended. He could not be roused, but he would take drinks. He was still lying with his arms flexed across his chest.

On September 2nd he did not seem to be so deeply comatose. His breathing had been Cheyne-Stokes in character at times during the night, but was now regular again, though stertorous. There were a few more petechial haemorrhages, still limited to the same area; there was no stiffness of the neck. The following day his condition was much the same. A lumbar puncture was performed, the fluid being quite clear and under normal pressure. On September 5th his general condition was much weaker. He would only drink at times, and was obviously dying. A

¹ *British Medical Journal*, April 15th, 1933.

further lumbar puncture was performed; the pressure of the fluid was slightly increased, and the analysis was: total protein, 45 mg.; total cells, 30 to 35 per c.mm.; dextrose content normal; culture sterile. The patient died on September 6th, seven days after the accident, having been unconscious for five and a half days.

A post-mortem examination showed the following: abdominal organs and heart normal; lungs congested; brain normal, no haemorrhage into its substance, and no extradural haemorrhage. It was noticed that the dura bulged just where the brain stem entered the cervical canal. On further investigation a blood clot was found between the bone and the dura mater in the upper cervical region laterally, not extending to the base of the skull. The lower limit was not investigated. The cervical vertebrae were exposed posteriorly, but no gross fracture was seen. The fracture of the leg bones was quite healthy. The interesting features of this case were: the petechial rash, sweating, temperature, and unconsciousness.

CAUSE OF DEATH

The anatomy of the region may help to show the cause of death. The vertebral arteries run up one on each side of the vertebral foramina from the sixth cervical to the axis. They then turn upwards to the foramina in the atlas. After passing through these they run backwards, piercing the posterior occipito-atlantoid ligaments and the dura mater to enter the cranium through the foramen magnum. In the vertebral foramina they are surrounded by a plexus of veins and branches of the sympathetic, and lie in front of the cervical nerves. The lateral spinal branches run through the intervertebral foramina into the vertebral canal and divide into (a) spinal branches ramifying on the backs of the vertebral bodies, and (b) medullary branches to the cord and membranes. The dura mater of the cervical canal is loosely adherent to the bony wall by areola tissue, and is not so firmly attached as inside the cranium. The position in which the patient lay with his arms flexed across his chest points to irritation of the sixth cervical nerve. The blood clot was seen at the level of the first cervical nerve, and so presumably extended down from C1 to C6. The petechial rash, occurring in the cutaneous distribution of C3 and C4, was probably due to irritation of these nerve roots, and this phenomenon has been observed in compression of the cervical cord. The sweating was mainly confined to the face and neck, and the pupils were moderately dilated; both were due to irritation of the cervical sympathetic.

Hyperpyrexia is known to occur in fractures and fracture dislocation of the cervical region. This is far removed from the recognized heat-regulating centre of the corpus striatum and the pons, and is also too low for the medulla to play any part in its production. An animal from which the sympathetics in the neck have been removed is unable to adapt itself to changes of temperature, so that irritation of the cervical sympathetic may have been the cause of the pyrexia. The only explanation I can offer of the cause of the mental changes and of the unconsciousness, which were present for six days before death, is that the vertebral arteries themselves were compressed by the haematoma either in the atlanto-occipital ligaments or within the cervical canal, giving rise to cerebral anaemia.

Death was due to haemorrhage from a medullary or spinal branch of the vertebral artery compressing the spinal cord above C4 and so paralysing the phrenic nerves.

Reviews

THE ANAEMIAS SURVEYED

Dr. JANET VAUGHAN describes her book on *The Anaemias*¹ as an attempt to review the present position of knowledge as regards anaemia. She has been fortunate in having the assistance of Professor H. M. Turnbull, who has written the descriptions of the normal and pathological anatomy of blood formation. Only those who have essayed a similar task will appreciate the amount of study, of thought, and of personal research which have gone to the making of this short book. It is a compact, critical, and up-to-date survey, which will be welcomed by the large and increasing number of workers who are interested in the advancement of knowledge in diseases of the blood.

In the bibliography reference is made to between three and four hundred papers, the great majority of which have appeared during the last ten years. This has been a period of revolutionary change in haematology, but though there may be disagreement about details, there will be general agreement with the main plan sketched out by Dr. Vaughan. In the opening chapter normal erythropoiesis is discussed, and the normal values of red cells and haemoglobin and other haematological data are summarized, special attention being paid to the size and haemoglobin content of the red cells. The anaemias are then classified into (1) the dyshaemopoietic anaemias due to failure or abnormality in blood production, (2) the post-haemorrhagic anaemias due to abnormal loss of blood, and (3) the haemolytic anaemias due to excessive destruction of blood in the organism. In the large section of the book devoted to the analysis and description of the anaemias due to deficiency of substances essential to the nutrition of the bone marrow we traverse what has now become familiar ground. Less familiar, and for that reason perhaps less convincing, are the suggestions that the severe anaemia sometimes associated with metastases in the bone marrow may be a deficiency anaemia, the cancer depriving the haemopoietic cells of necessary food factors; or that acholuric familial jaundice may be due primarily to some disturbance in the metabolism or nutrition of the red cells.

The book is not intended to be a primer on haematology, and conditions such as leukaemia and the haemorrhagic states are discussed only in so far as they involve the erythron. It is a monograph for the research worker, the pathologist, and the consultant physician, who will find in it a mine of carefully documented information, which is presented clearly and interestingly, and which cannot fail to stimulate haematological research.

LATENT SYPHILIS

Essays on Chronic and Familial Syphilis,² by GRIFFITH EVANS, should cause a considerable flutter in medical dovecotes, for the author has the courage to tell us that we are constantly missing the diagnosis of syphilis through being so hidebound and blind. He points out that the disease is one of the lymphatic system first and last, and that consideration of this fact will explain many of those obscure signs and symptoms which puzzle us so often and which he ascribes to latent syphilis.

Starting on the assumption that there is a cycle in the life of the *Treponema pallidum*, he considers that many of

¹ *The Anaemias*. By Janet M. Vaughan, D.M., M.R.C.P. With Notes on Normal and Pathological Erythropoiesis by Hubert M. Turnbull, D.M., F.R.C.P. London: H. Milford, Oxford University Press, 1934. (Pp. 245. 12s. 6d. net.)

² *Essays on Chronic and Familial Syphilis*. By Griffith Evans, M.A., D.M., F.R.C.S. Bristol: J. Wright and Sons Ltd.; London: Simpkin Marshall Ltd. 1934. (Pp. 91; 13 figures. 7s. 6d. net.)

the so-called meta- and para-syphilitic manifestations are due to the "granules," and that latent syphilis is the cause of many chronic complaints, the diagnosis of which is frequently missed, and quotes as examples nervous dysphagia, basal congestion of the lungs, various forms of glossitis, and the "chronic abdomen." The evidence that these are attributable to syphilis is often weak, because the Wassermann reaction may be negative, the *Treponema pallidum* not demonstrable, and no pathognomonic lesions evident, but it is the therapeutic response which matters and which is of such importance to the general practitioner.

On the subject of the Wassermann reaction the author has some very wise remarks to make: this test has become a "master" and not a "servant"; many people think a negative reaction excludes syphilis; and "the diagnosis of syphilis is more often missed because a Wassermann reaction is negative than made because the reaction is positive." One way of approaching the problem of the diagnosis of latent syphilis is to observe the signs and symptoms in those who have it, and to argue from these its presence in those who may have it.

This little book is composed of matter that is largely of a highly controversial nature, and many of the opinions expressed are revolutionary; but it is refreshing to read the work of a man who has evidently given much thought and observation to his subject. Not all that is written must be taken for "gospel"—one might be led to believe that most of us are syphilized—for many of the arguments are rather unconvincing, while some of the deductions are made on what appear to be doubtful premisses. But at least we are given food for thought, and if a few bismuth injections or some mercury and potassium iodide will clear up the symptoms the practitioner will gain the gratitude of his patient, and if he fails he will have done no harm; we are not told much about failures. The author, like the Russian Socialists, may be ahead of his time, but perhaps he will help to lift some out of the "slough of despond."

ORAL SURGERY

Professor MEAD's *Oral Surgery*³ has been compiled as the complement of his treatise, *Diseases of the Mouth*. That dealt with diagnosis; this deals with the actual surgery. The book is intended for everyday dentists and for students, and very wisely the author limits himself almost entirely to the minor surgery of the mouth. (Most pertinently he notes in his preface that, strictly, there is no such thing as *minor surgery*.)

At first sight, with its 1,000-odd pages and forty-seven chapters, it appears a formidable tome, and one wonders whether oral surgery, major and minor together, can possibly be stretched to such lengths. Apprehension on this score, however, soon vanishes; indeed, one often wishes the author had been more expansive, for the book is a record of wide experience by an acute observer. The first 300 pages are devoted to diagnosis, surgical anatomy, choice of anaesthetic, preoperative preparation, sterilization (in this chapter the author points out that, since spores have no means of attaching themselves to anything, scrubbing in running water may be relied on to remove them, while the actual vegetating organism is as easily killed as any other organism) inflammation, surgical bacteriology, and kindred subjects. All are treated in a clear, practical fashion. The remaining 700 pages deal with oral surgery proper and, with the exception perhaps of cleft-lip and cleft-palate and bone-grafting, with conditions any dentist in "general" practice may be called upon to treat. It is interesting to note the author's qualified approval of such operations as

replantations and apicectomy, and his not quite convincing defence of alveolectomy. The chapter on removal of foreign bodies should be read by all who are likely to be called on to remove broken hypodermic needles from the jaws. That on fractures gives, we think, almost too hopeful a view of the fate of alveolar fragments carrying teeth. Necrosis receives but short notice, though its precursor, acute osteomyelitis, is fully dealt with; and rightly so, since a necrotic termination may sometimes be averted and often minimized. We agree with the author that there is no ground for incriminating extraction during the acute stage as a cause of subsequent necrosis. He seems to imply that *Staphylococcus pyogenes aureus* is the most frequent causative organism, but this is contrary to our experience.

The chapter on "Periodontal Disease" gives a reasoned summary of the various methods of surgical treatment of this disease, with perhaps too little appreciation of the *vis medicatrix naturae*. In a note on osteomalacia Professor Mead states that there may be "a softening or disintegration of tooth structure" in this disease: it would be of great interest to have this observation confirmed. The explanation of the aetiology of protrusion of the mandible offered on page 753 seems to us very open to question, as also is the claim that syphilis and tetanus are the chief causes of macroglossia (page 49). Under the heading "urinalysis" we should like to see a notice of acetone. The illustrations are numerous and to the point, though there are some (for example, on pages 493 and 956) which seem to need more explanation. But this is a big work, and contains a large amount of valuable information.

POISONOUS PLANTS OF SOUTH AFRICA

The Toxicology of Plants in South Africa. Together with a Consideration of Poisonous Foodstuffs and Fungi,⁴ by Dr. DOUG G. STEYN of the Onderstepoort Laboratories (Transvaal) gives a general review of stock poisoning and a comprehensive account of the researches on this subject that have been prosecuted for many years at the Veterinary Institute at Onderstepoort.

South Africa is afflicted with a wide variety of stock poisons, which constitute a serious problem in agriculture. One species alone is credited with the death of a million sheep in two years, while certain species of *Senecio* have made horse-breeding impossible in certain areas. Consequently a large amount of time and money has been devoted to the investigation of stock poisons. Fortunately these poisons are rarely the cause of human death or disease, but the extensive and elaborate toxicological investigations carried out at Onderstepoort have provided much information of general interest to pharmacology and toxicology. For example, the powerful actions of ergot (*Claviceps purpurea*) are familiar in human therapeutics, but it is interesting to learn that for practical purposes all fungus-infected foodstuffs must be considered poisonous until the contrary has been proved, since it would appear that a host of unknown active principles are produced by other fungi.

The bulk of the volume is occupied by the botanical description of toxic plants, together with an account of their effects. Some of these actions are of much general interest. Thus there are instances of delayed poisoning, such as stagger-weed, which gives rise to symptoms after a latent period of three to eight weeks. Some plants are noteworthy because they induce photo-sensitization. Another plant, when eaten by pregnant goats, causes alopecia in the kids, but when given directly to newborn

⁴ *The Toxicology of Plants in South Africa. Together with a Consideration of Poisonous Foodstuffs and Fungi*. By DOUG G. STEYN, B.Sc., Dr. Med. Vet. (Vienna), D.V.Sc. South Africa. Central News Agency Ltd.; London: Gordon and Gotch Ltd. 1934. (Pp. xii + 631; 135 figures. £2 7s. 6d.)

³ *Oral Surgery*. By Sterling V. Mead, D.D.S., M.S., B.S. London: H. Kimpton. 1933. (Pp. 1087; 403 figures. 63s. net)

kids it does not produce poisoning. Perusal of the book reveals a most remarkable variety of toxic actions. Though he is particularly concerned with South African stock poisonings, the author has made a general review of the literature, and provides a bibliography of some twenty-eight pages. The publishers are to be congratulated on the get-up of the volume, and in particular on the excellence of the numerous illustrations.

ESSAYS ON SURGICAL TECHNIQUE

HENRY DELAGENIÈRE was born in Paris in 1858. He came from an old Protestant family, and was a direct descendant of Pierre de la Gelière, a friend of Ambroise Paré and Admiral de Coligny. After a brilliant career in Paris, where he was the house-surgeon of Lucas Championnière and of Terrier, he boldly left Paris and settled down at Mans. It was at the instigation of Terrier that he decided to develop in the French provinces a centre for the study of aseptic surgery, which was then in its infancy, and in that development Terrier himself showed very practical interest.

The volume, entitled *Cinquante Techniques Chirurgicales*,⁵ records the personal observations of a surgeon of brilliant originality, who entered surgery at the commencement of a new technique, to become, ultimately, one of its greatest masters. It consists of a series of studies which range over the whole of surgery, from gastrectomy to the transplantation of the ureters, and from Caesarean section to suture of a fractured patella. In every case the problem is attacked from an original standpoint, and there is evident in every instance the vast experience of a master of his art. Almost every study is well illustrated, and the quality of the illustrations and the minute care with which technical details are elaborated show an appreciation of technique for its own sake which to-day is only too rare.

It is not to be expected that one should agree with all the methods described, but we venture to think that there is no surgeon so experienced that he will not learn something from a perusal of every single one of these studies. To the experienced surgeon who wishes to improve his technique we would most strongly recommend it as one of the most stimulating series of essays we have met for some time.

DINOSAURS AND THEIR DISEASES

The story of the dinosaurs, so far as it is known at present, has been excellently told by Dr. W. E. SWINTON,⁶ who is a member of the geological staff of the British Museum. No doubt the interest which the public is now taking in the possible survival of Mesozoic monsters may have suggested the appearance of the work, but the purpose served is certainly not ephemeral. Dinosaurs began to appear in the world at the beginning of the Mesozoic (Secondary) period, some 180 million years ago, and after flourishing in all parts of the world, and assuming an infinity of forms, mysteriously vanished as mammalian forms began to appear at the end of the Mesozoic. The Dinosaur order, which sprang from that reptilian stem which gave rise to crocodiles on the one hand and birds on the other, came to an end after an existence of 120 millions of years. Dr. Swinton discusses very fully the possible causes of their extinction, favouring that which attributes the final catastrophe to overspecialization, with a complete loss of all power to

undergo structural and physiological adaptation to changes in environment. The bigger dinosaurs had a body as large as that of an elephant, but their brains were no greater in size than that of a kitten. Possibly a fuller understanding of the part played by hormones in the evolution of new forms of life will explain certain aspects of the great dinosaur tragedy which are now obscure to us. Dr. Swinton devotes a chapter to the bone diseases of the dinosaurs, drawing on the descriptions of pathological specimens published by Dr. Roy Moodie, as well as upon his own observations.

Notes on Books

Manometric Methods,⁷ by Dr. MALCOLM DIXON, is a short laboratory handbook giving precise details of the methods devised for the measurement of cell respiration. Sir F. Gowland Hopkins, in a foreword, points out the significance of the results that have been attained from the development, by Warburg and others, of methods for measuring the respiration of micro-organisms and of small pieces of tissue. These delicate micro-methods have provided results of great importance in an exceptionally wide field, for they are used by biochemists, physiologists, bacteriologists, pathologists, and zoologists. The disadvantage of these methods is that the results are valueless unless scrupulous attention is paid to technical details. Dr. Dixon has a large experience in the use of micro-manometric methods, and his handbook provides an excellent guide for those wishing to master this difficult technique, and it will be of great value to research workers in many fields of experimental science.

Dr. PINEY, a recognized writer on haematology, has summarized in a clearly written "pocket-monograph" modern knowledge in *Blood Diseases in General Practice*.⁸ The forms of anaemia, especially those in the young, have recently been so elaborated that the general practitioner will find this a useful guide not only in explaining the new nomenclature but also in employing suitable treatment. As an example of the up-to-date character of this small volume attention may be specially drawn to the account and treatment of agranulocytosis in the last chapter.

In his essay on *Social and Personal Factors in Chronic Alcoholism*,⁹ which forms the third instalment of the series of psychiatric and neurological monographs emanating from the Neurological Clinic of the Charité Hospital of Berlin, Dr. KURT POHLISCH gives an interesting picture of the attitude towards the drink question at the present day among the various classes of society in Germany. In the first place, the change in the political situation has had a favourable effect on the decline of alcoholism, especially among the labouring classes, the students, and, to some degree, the Army. Other factors in the decline in alcoholism in Germany are the cinema and interest in athletics. With regard to the personal factors which are responsible for alcoholism Dr. Pohlisch brings forward statistics for the Charité Hospital, Berlin, for the period 1919-31, showing that 75 per cent. of chronic alcoholic subjects have some form of psychopathy, while most of the normal are of cyclothymic temperament.

The first edition of LANGERON'S *Précis de Microscopie* was published twenty years ago. It has gradually grown in size and in usefulness, and the fifth edition,¹⁰ which has now appeared, contains much new matter. Labora-

¹⁰ *Précis de Microscopie*. Par M. Langeron. Fifth edition. Paris: Masson et Cie. 1934. (Pp. 1,208; 355 figures. Broché, 86 fr.; cartonné toile, 100 fr.)

tory workers in all parts of the world have come to regard Langeron's handbook of microscopical technique as an indispensable reference book, in which one is very likely to find the odd little bit of information which one has searched for through other books in vain.

We have received the fifth volume (1933) of the *Annals of the Clinic for Mental and Nervous Diseases of the Royal University of Palermo*,¹¹ an institution under the direction of Professor Colella Rosolino, which has recently acquired new and larger accommodation after an existence of some thirty years. The compilation includes forty-four articles relating to original work undertaken in the clinic, and dealing with such diverse topics as goitre-producing waters, alterations in the cerebro-spinal fluid, extrapyramidal syndromes, diathermy in neurological diseases, traumatic neurosis, the pathogenesis of multiple sclerosis, and serotherapy in infantile paralysis. These articles are bound

¹¹ Palermo: Industrie Riunite Editoriali Siciliane. 1933.

together, and several are illustrated by plates and diagrams, the whole forming an admirable indication of the work in progress at a pioneer institution in the fields of neurology and psychiatry.

The eleventh issue of the *Proceedings of the University of Otago Medical School* is dated 1934, and has been edited by Professor D. W. CARMALT JONES. It contains a series of scientific publications by members of that University which have appeared in various periodicals, and an account of the British Medical Association in New Zealand, contributed to the *Canadian Medical Association Journal* in 1932. The volume opens with the George Adlington Syme Oration for 1933, which was delivered by Professor Gordon Bell, and was the second of the series. It deals mainly with the hospital problems and the education of the surgeon. Ten out of the dozen articles deal with topics of clinical interest, three relating to radium therapy.

Preparations and Appliances

MINIATURE PNEUMOTHORAX APPARATUS

Dr. JAMES MAXWELL (London, W.1) writes:

This instrument has been constructed for me by the Genito-Urinary Manufacturing Company, and has been in routine use for the past six months, during which time it has given satisfactory results.

The apparatus consists of four essential parts—the pump, the regulating valve, the aneroid manometer, and the filter. These parts are contained in a cabinet 7 in. by 4 in. by 8 in., and the total weight is 6 lb. The pump has a capacity of 200 c.cm., and is made entirely of metal. The combined weight of the piston, piston-rod, and two-way cock is calculated to produce a gas pressure equal to a column of

water of 35 cm. The piston-rod is hollow, and is fitted with a two-way cock of convenient shape to act as a handle by which the piston is pulled up. One end of this cock terminates in a screw cap for the purpose of holding a cotton-wool filter for the aspirated atmospheric air. The opposite end is bent downward, and is joined to the regulating valve by rubber tubing. By means of this valve the rate of flow of the air to the pleura can be controlled with great ease and accuracy within wide limits, or it can be cut off entirely. From the outlet port of the regulating valve the tube divides into two branches. One leads via the filter to the patient, and the other to an aneroid manometer. The quantity of air which has passed to the chest is indicated on the outside of the piston-rod by a double scale graduated by 20 c.cm. from 0 to 200 c.cm. The filter is a little more elaborate in design than is usual with existing apparatus, but the frequent and convenient change of the cotton-wool packing which is possible justifies the elaboration. It resembles the Record syringe, and consists of a glass tube with a metal cone at one end and a screw cap at the other. The ground metal cone fits into a counterpart, which is part of the "T" junction connecting the manometer and filter to the regulating valve. When the wool is to be changed the filter is removed from the clip which holds it to the wall of the cabinet, and is then disconnected from the "T" piece. The

cap is then unscrewed and the wool changed. The whole process is carried out without disturbing the rubber tubing.

The manometer is specially constructed, and has been subjected to severe tests extending over two years in order to ascertain its constant accuracy. The scale is well spaced, and the pressures can be read easily; the instrument appears to be more sensitive than the water manometer. A suitable winder for the rubber tubing and a detachable rack for the needles are fixed inside the door of the cabinet. The most suitable lubricant for the piston has been found to be ordinary medicinal castor oil.

The advantages claimed for this instrument are that it

is readily portable, there is little likelihood of accidental damage, it is always ready for use, and the difficulties inseparable from the use of liquid in the manometer are obviated. When used for a refill the instrument is placed upright, the cylinder is filled with atmospheric air, and the flow to the chest is regulated by the special valve, so that any desired pressure can be maintained; the pressure is constantly indicated by the manometer, and the flow of air can be instantly stopped by closing the valve.

For the induction of a pneumothorax, in which case it is necessary that the first part of the air should be drawn into the chest by the suction of the collapsing lung, the instrument is placed on its back so that the cylinder is horizontal. It has been found that a negative pressure of only 3 or 4 cm. of water is sufficient to move the piston, and so draw air into the chest. For the withdrawal of air from the chest the reverse process must be carried out, the air being drawn from the chest to the cylinder by suction. The filter must, of course, always be changed before the instrument is again employed for refills.

It is a pleasure to express my thanks to Mr. R. Schranz of the Genito-Urinary Company for the very great help which he has given me with the details of the design of the model, as well as the care and skill which he has devoted to its construction.

CLASSIFICATION OF MENTAL DISORDERS

BY

G. W. T. H. FLEMING, M.R.C.S., D.P.M.ENG.
HONORARY SECRETARY, CLINICAL PSYCHIATRY SUBCOMMITTEE,
ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION

In 1929 the Clinical Psychiatry Subcommittee¹ of the Royal Medico-Psychological Association began the revision of the existing official classification. This revision has been completed and accepted by the Royal Medico-Psychological Association as its official classification, and is here presented.

The scheme consists of two parts, intended to be used in conjunction with each other. Part I contains the actual classification and Part II the aetiological factors, or associated factors, as some may care to call them.

The revision of the aetiological factors has enabled the subcommittee to limit Part I as far as possible to a purely clinical classification—that is, one presenting clinical pictures or types of mental disorder with which all psychiatrists are familiar. Except in a very few well-defined instances, referred to later, terms with an aetiological connotation have been excluded from Part I. Further, an attempt has been made to make the classification sufficiently elastic to allow of future developments. For this reason the table consists of a limited number of broad headings, rather than an exhaustive inventory of syndromes and subgroups. Where, however, a patient is found to be suffering from a particular syndrome which is not adequately described under a group-heading, it is stipulated that this is to be specified. For instance, a case of Korsakov's syndrome should be returned as "confusional state (Korsakov's syndrome)," and if the condition is deemed to be due to alcohol, the complete classification, expressed in symbols for statistical purposes, would be F (Korsakov's syndrome) S A a.

The headings under which such subtypes are likely to occur, or should be specified, have been indicated by an asterisk. Similarly, a number of the headings in Part II have been marked with an asterisk, and in these cases the precise aetiological factor is to be specified, when known. Thus a psychosis due to cerebral tumour should appear as I 10 (cerebral tumour); a case of depression following influenza and associated with a family history of manic-depressive psychosis would appear as E a ii. S B c & 1 a (manic-depressive).

CLASSIFICATION OF MENTAL DISORDERS—PART I
To be Used in Conjunction with Part II
(The Aetiological Factors)

- A. Oligophrenia (amentia, mental deficiency).
 - (a) Idiocy.
 - (b) Imbecility.
 - (c) Feeble-mindedness (moron).
 - (d) Moral deficiency.
- B. Neuroses and psychoneuroses.
 - (a) Exhaustion states (including neurasthenia).
 - (b) Anxiety states.
 - (c) Compulsions, obsessions, and phobias.
 - (d) Hysteria.
 - * (e) Mixed and other forms.
- C. Schizophrenic psychoses.
 - (a) Dementia praecox.
 - (i) Simple. (ii) Hebephrenic. (iii) Katatonic. (iv) Paranoid.
 - (b) Paraphrenia.
 - * (c) Other forms.
- D. Psychopathic constitution (including paranoia).
- E. Affective psychoses.
 - (a) Manic-depressive psychosis (cyclothymia).
 - (i) Elation. (ii) Depression. (iii) Stupor.
 - (b) Involutional melancholia.
- * F. Confusional states.
- G. Epileptic psychoses.
- H. General paralysis.
- * I. Other psychoses associated with organic brain disease.
- * J. Dementia.
- * K. Undetermined types.

* Specify type when possible—for example, Korsakov's syndrome.

CLASSIFICATION OF MENTAL DISORDERS—PART II

1. Heredity.
 - * (a) Psychotic.
 - (b) Epileptic.
 - * (c) Neurotic.
 - (d) Alcoholic.
 - * (e) Various organic nervous diseases.
 - * (f) Endocrine disease.
 - (g) Tuberculous.
2. Deprivation of special sense.
 - (a) Sight.
 - (b) Hearing.
3. Critical periods.
 - (a) Puberty.
 - (b) Adolescence.
 - (c) Climacteric.
 - (d) Senility.
4. Child-bearing.
 - (a) Pregnancy.
 - (b) Puerperium (not septic).
 - (c) Lactation.
5. Mental factors.
 - (a) Previous attacks of mental disorder.
 - * (b) Sudden stress.
 - * (c) Maladjustments of—
 - (i) Social life.
 - (ii) Sex life.
6. Physiological disturbances.
 - (a) Malnutrition.
 - (b) Privation.
 - * (c) Exhaustion.
7. Trauma.
 - * (a) Injuries.
 - * (b) Operations.
 - (c) Sun- or heat-stroke.
 - (d) Electric shock.
8. Toxic factors.
 - A. Chemical.
 - (a) Alcohol.
 - * (b) Narcotic drugs.
 - * (c) Mineral poisons.
 - * (d) Other poisons.
 - B. Infective.
 - (a) Syphilis.
 - (i) Congenital.
 - (ii) Acquired.
 - (b) Puerperal fever.
 - (c) Influenza.
 - * (d) The specific fevers.
 - (e) Tuberculosis.
 - * (f) Focal sepsis.
 - * (g) Other infections.
 - * C. Metabolic.
- * 9. Deficiency diseases (pellagra, beri-beri, etc.).
- * 10. Diseases of the nervous system.
11. Diseases of other systems.
 - * (a) Haemopoietic system.
 - * (b) Cardiovascular system.
 - * (c) Respiratory system.
 - * (d) Gastro-intestinal system.
 - * (e) Genito-urinary system.
 - * (f) Endocrine system.
12. No factor ascertained.
13. No history obtained.

Additional Notes

The following definitions and explanatory notes have also been adopted for the guidance of those using the classification.

A. *Oligophrenia (Mental Deficiency)*.—A condition of arrested or incomplete development of mind, whether arising from inherent causes or induced by disease or injury.

B. *Neuroses and Psychoneuroses*.—No differentiation is here made between the two conditions.

* To be specified.

(a) This should designate abnormal mental states characterized essentially by mental or motor fatigability and irritability.

(b) This includes the symptoms commonly exhibited by generalized fear.

(c) In this group should be included phobias, where the anxiety is attached to some definite object or situation.

(d) Is a faulty reaction to environment characterized by a variety of (1) motor symptoms, (2) sensory symptoms, (3) mental symptoms.

c. *Schizophrenic Psychoses*.—This syndrome includes cases which show remissions, and even recoveries, in addition to cases which show progressive deterioration.

(a) *Dementia praecox*.

(i) Simple: Cases characterized by defects of interest, gradual development of an apathetic state, often with peculiar behaviour, but without expression of delusions or hallucinations.

(ii) Hebephrenic: Cases showing prominently a tendency to silly laughter, grimacing, mannerisms, together with grotesque ideas and erratic behaviour.

(iii) Katatonic: Cases in which there is a prominence of negativistic reaction or peculiarity of conduct, with phases of stupor or excitement, sometimes characterized by impulsive or stereotyped behaviour, and usually hallucinations.

(iv) Paranoid: Cases characterized by unsystematized delusions, usually of persecution or grandeur, hallucinations in various fields, and a tendency to early dementia.

(b) *Paraphrenia*: Cases in which emotional and volitional disorder is slight. Delusions and hallucinations generally grandiose and fantastic, but with little effect on ordinary conduct.

d. *Psychopathic Constitution*.—This group includes a large group of pathological personalities such as are found among criminals, tramps, sex perverts, drug addicts, matroids, agitators, etc. The true prison psychoses should be included in this group. *Paranoia*: A delusional syndrome of insidious development. Hallucinations are absent, and there is no deterioration.

e. *Affective Psychoses*.—Involuntary melancholia comprises the slowly developing depressions of middle life and later years characterized by worry, insomnia, uneasiness, and agitation. States of depression in arteriosclerosis should be excluded.

g. *Epileptic Psychoses*.—This group includes only what is known as essential epilepsy. Cases of organic brain disease, with seizures of any kind, are not to be included.

h. *General Paralysis*.—Cases of cerebral syphilis are excluded.

j. *Dementia*.—This group does not include the dementias where the original condition is known. The arteriosclerotic and presenile dementias are to be included in Group i.

Commentary

Some of the items dealt with above call for further comment.

A. *Oligophrenia*: The term "amentia" is open to very grave objections. In the first place, few of the cases included present an "absence of mind," so that it is an inaccurate term. The word was first introduced by Meynert as a name for a condition which we to-day call "confusional insanity." It is used in this sense in the Norwegian and Dutch classifications. The Italians use "amenza" as one of their subdivisions of "tossinfettion ed autointossicazioni," and divide it into "allucinatoria, apatica, lieve (pazzia sistematizzata acuta), gravissima (delirio acuto)." The clinics of Pilcz and Wagner-Jauregg in Vienna both used the word in the confusional sense. Shaw-Bolton used the word to correspond with "dementia" (meaning "out of the mind"), his amentia being defined as "the mental condition of patients suffering from deficient neuronic development." The Greek word "oligophrenia," meaning "small mind," was adopted by Bleuler, and is also in the Dutch classification. This term is certainly not used in any other sense than for all classes of mental defectives. It is hoped that medical men will encourage the use of the word, and that the inaccurate and ambiguous "amentia"

will be dropped. "Amentia" is retained in brackets simply as a guide in the meantime.

B. The terms, "neuroses" and "psychoneuroses" were preferred to the expression "minor psychoses."

(a) The word "neurasthenia," for which many confess a liking, was rejected, as it was so very loosely used during the war as a dumping-ground for all sorts and conditions of mental disorders. Freud also uses the word in a restricted sense in connexion with masturbation. The expression "exhaustion states" was thought to convey a very definite meaning, and to indicate a fairly clear-cut clinical condition.

(c) Phobias have been separated from the anxiety states on the grounds of a fundamental difference between the vaguer, more indefinite, and generalized fears of the latter and the definite attachment of fear to an object in the former.

(b) and (d) call for no special comment.

c. The word "schizophrenia" has come to occupy a permanent place in our vocabulary. The paraphrenic conditions, it was thought, ought to be separated from what we are used to calling dementia praecox. The time-honoured division into simple, hebephrenic, katatonic, and paranoid types was adhered to.

d. The paranoiac conditions which do not end in intellectual impairment should, it was thought, be sharply separated from the schizophrenic psychoses.

e. This section does not call for much comment. It was thought that the involutional states were more closely allied to manic-depressive insanity than to the schizophrenic conditions.

Section c is an unsatisfactory group, and will undoubtedly be subdivided as knowledge advances, but in the meantime it is retained to correspond to what is called "essential" epilepsy with psychosis. Obviously, however, an epileptic may remain sane, or may develop some other form of insanity, such as manic-depressive psychosis.

Section h (general paralysis) is a recognized clinical group, although purists may not agree with the diagnosis, as sometimes made. Here again our knowledge is not sufficiently advanced to permit of any alteration.

i. The expression "the psychoses associated with organic brain disease" was intended to correspond with the present "insanity with gross brain lesion." It was felt that there was no need to separate off more than the syphilitic conditions.

k. The last division was left for conditions which could not be classified under any of the divisions a to j.

I cannot close these notes on the work of the subcommittee without expressing indebtedness to the late Dr. J. R. Lord. No one who has not had the pleasure of working with him can appreciate the extraordinary amount of work he did, or the help and encouragement he gave to the younger men. Although he did not live to see the completion of this classification, his was the moving spirit in the last two years' work.

REFERENCE

¹ This subcommittee at the time the classification was finally adopted consisted of the following members: Sir Hubert Bond (Emeritus Lecturer on Psychiatry, Middlesex Hospital), J. Brander, L. C. F. Chevens, K. K. Drury, W. Norwood East (Prison Commissioner), F. L. Golla, W. McCartan, Professor D. K. Henderson (Professor of Psychiatry, Edinburgh University), P. K. McCowan (Lecturer in Mental Diseases, Welsh National School of Medicine), D. McRae, W. F. Menzies, J. E. Nicole, W. D. Nicol (Lecturer on Psychiatry, London School of Medicine for Women), A. A. W. Petrie (Lecturer on Mental Diseases, Charing Cross Hospital and West London Post-Graduate College), M. Hamblin Smith, W. H. B. Stoddart, W. S. J. Shaw, B. H. Shaw, A. Walk, H. Yellowless (Lecturer on Psychological Medicine, St. Thomas's Hospital), and the Honorary Secretary.

F. Bamatter (*Arch. f. Kinderheilk.*, March 31st, 1934) states that, whereas up to September, 1932, isolated cases of facial paralysis were rare, and actual bulbar paralysis was unknown, during the subsequent twelve months six sporadic cases of the bulbo-pontine form of infantile paralysis were observed in the University Children's Clinic at Zürich. There was, moreover, a simultaneous increase in sporadic cases of encephalitis and aseptic meningitis. In two very acute cases of bulbar paralysis the diagnosis was confirmed by inoculation of monkeys.

SOVIET MEDICINE AGAIN

It is very difficult for people in this country to keep an open mind about the course of events and of ideas in the Red Republics; without comprehensive first-hand knowledge we grope in the dark. Prejudice—if not propaganda—for or against the Soviet regime seems to run through almost every book and article on the subject. During August and part of September, 1932, Sir Arthur Newsholme and Dr. John Kingsbury, secretary of the Milbank Memorial Fund, travelled in Soviet Russia. Equipped with letters of introduction from Lord Passfield and Senator Borah they entered Soviet territory from Poland, and, moving by way of Moscow and Nijni Novgorod to the Volga, steamed down that river for four days. After visiting Tiflis they came to the Black Sea at Batum, took steamer from there to the Crimea, and returned by rail through the Ukraine to Moscow. In the course of their journey they saw much, and, though unacquainted with the Russian language, received much information. They have presented their impressions in a work entitled *Red Medicine*,¹ one half of which is mainly devoted to an exposition of Russian Communism, while the other half deals more specifically with the subject of the title.

In approaching the investigation of health conditions in Russia the authors take the view that the present-day framework of Russian society closely concerns the subject of their inquiry, just as it concerns every other human activity within the circuit of the seven Republics. They show how each Republic possesses in varying stages an electoral system, the chief utility of which is to divert the minds of the factory hands and peasants with engrossing but ineffective discussion. All power is in the grasp of the Communist party, working centrally through a dictatorship and locally through a secret police organization which tries, condemns, and executes at discretion. No person can join the party unless he renounces his religious faith. Owing to the intense overcrowding in houses, together with the facility of divorce and the ample provision of crèches for children, family ties are obsolescent. It is the aim to displace the family, and to substitute the factory as the focal point of communal life, providing thus, on a self-contained basis, for work, rest, and cultural development, as well as for hygiene and medical treatment at an attached health centre. The authors cite as an instance of an "admirably controlled" establishment of this kind the Selmarshstroy factory at Rostov-on-Don, which is made up of eighteen works, each employing about a thousand people. Workers there

are systematically examined by the works doctors, and according to their needs are relegated for treatment to a dispensary, polyclinic, specialist clinic, general or special hospital, venereal disease hospital, tuberculosis sanatorium, or night sanatorium, the last being a dormitory for those who, though able to do some work, stand in need of special care. The Unitary Dispensary at Rostov, the authors say, is an exemplary institution: it is described by them as admirably equipped in all special departments of medicine. At Kharkov they viewed the Third Labour Polyclinic, a "magnificent new building," with special departments for a wide range of clinical work, and "admirably equipped" for research as well. They thought that the hospital for railway employees at Tiflis, in the obstetric division of which there are special rooms for confinement, was "splendidly organized." They were astonished at the "vast provision," along the Black Sea coast and elsewhere, of rest-houses, convalescent homes, and sanatoria, once the palaces of Russian nobles.

The Soviet rulers, given time, could doubtless, like Trajan, build their world over, this task having been simplified at the outset by the adaptation to medical uses of many handsome existing structures no longer claimed by their owners. Their enterprise, their determination, and their vision for health in Russia were under notice in these columns last December, when we commented on a brochure by Dr. A. Roubakine of Moscow. In point of organization and equipment Sir Arthur Newsholme and Dr. Kingsbury confirm what Dr. Roubakine had already told us. They recount also as an example of Soviet efficiency that the entire population of the town of Kazan, numbering 179,000 persons, were vaccinated or revaccinated in June, 1932, following the occurrence of fifteen cases of small-pox in the previous winter. Buildings, equipment, and organization, however, are but the outward seeming of a medical service: its substance, content, and inspiration cannot be appraised by these externals, but only by the inherent quality of the medical work of which they are the setting. On this inherent quality, which is the true soul of medicine, the authors in dealing with Soviet Russia are not convincing. It may be that the genial flower of medicine blooms with difficulty in the stark and rigorous atmosphere of Communism. It may be that in the time at their disposal the travellers had not the opportunity to explore closely the effective content of medical practice in the various towns they visited.

But any uncertainty as to the medical standards would have been appreciably dispelled had the authors been able to supply pertinent information regarding the medical curriculum now or lately engaged in by Soviet students of medicine. The ranks of the profession in Russia as elsewhere must be presumed to be recruited from the medical schools, and the ideals of the schools should in consequence set the pace for the practising doctor. But here again the authors are reticent. Medical teaching is lightly touched on, and what little is said mainly relates to such incidentals as

¹ *Red Medicine: Socialized Health in Soviet Russia*. By Sir Arthur Newsholme, K.C.B., M.D., and John Adams Kingsbury, LL.D. London: William Heinemann (Medical Books) Ltd. 1934. (10s. 6d. net.)

the manner in which candidates are selected to begin study. The note that during his first year the student "assists in minor medical and surgical work, including cleaning up after the work is completed" is not reassuring. Dr. Roubakine, above referred to, is more communicative. Medicine, he says, is tripartite in Russia. It is studied under three specialisms. The courses last from three and a half to four years, with a further year of probationer service, and besides medicine include social science, economics, and the Marxian philosophy, military training, and the acquisition of materialistic views. Whatever the medical content of the curriculum the student is apparently not at liberty to devote his undivided attention to it. The conclusion seems warranted that the young Russian doctor at the present time is less well trained in medicine than his contemporaries in Western Europe, and that the medical services of the Union must in consequence be affected prejudicially. The Soviet Government, which controls all medical teaching, will no doubt effect reform in this field also, but the task will not prove quite so easy as the equipment of buildings and the organization of services.

The authors claim that in making their investigations they had no previous bias, "except some measure of scepticism as to the possibility of the Western world deriving useful lessons from Eurasia." Some examples of their lavish praise of Soviet undertakings have been quoted above. In one passage elsewhere they strongly deprecate the class hatred systematically instilled into the mind of the young Russian; but in sundry other matters where Soviet conduct has outraged Western feeling they assume an air of detachment which will surprise most English readers. Whether a polity under which there is nothing for a man to worship but the material things his own hands have made, does or does not carry within it some inevitable seeds of decay, the Soviet Government in the meantime has achieved much in health organization, and may be expected to achieve more, even to the extent of establishing throughout a great part of its territory medical services which, though ranking below Western standards, will be competently mass-productive of physical efficiency. In this way it will further the plan of the despotic Communist Party, which is to provide for labour and defence—the two key words of Communist teaching—from the kindergartens onwards.

ALLERGY AND IMMUNITY IN TUBERCULOSIS

Discussion on the relative parts played by allergy and immunity in the defence mechanism of the host against tuberculosis is reminiscent of the old controversy which raged between the protagonists of the humoral and those of the cellular theory of immunity. The present conception of immunity to infection rests on both a cellular and a humoral basis. The preliminary sensitization, mechanical clumping, and some-

times lysis of the bacteria appear to be dependent on antibodies which are either free in the circulation or are concentrated on the surface of the tissue cells, while the ingestion of the bacteria, their removal from the circulation, and their subsequent disintegration are accomplished mainly by phagocytic cells of various types. Generally speaking, the presence of a high content of circulating antibody is indicative of a considerable degree of immunity, while when the antibodies are present in just sufficient quantity to satisfy the demands of the cells the immunity is of a lower grade. There is evidence to suggest that the meeting of antigen and antibody on the surface of the cells is often accompanied by a severe reaction of anaphylactic type, while when the union occurs in the circulation this type of reaction is forestalled.

There seems to be no valid reason for excluding resistance to tuberculosis from this general picture. The evidence so far accumulated seems to be compatible with the view that allergy represents a stage in the development of immunity when the antibodies are concentrated mainly on the surface of the cells; whereas so-called immunity is a stage further on, when there is some free antibody in the circulation, and the local disturbances caused by the meeting of antigen and antibody in the tissues are therefore less severe. This conception, however, does not seem to be in the minds of many of those who are working experimentally on tuberculosis. Largely owing to the views put forward by Rich, attempts are now being made to dissociate allergy from immunity. One of the methods of doing this is described by H. Rothschild, J. S. Friedenwald, and C. Bernstein¹ in a study of tuberculous infection in guinea-pigs, and consists in desensitizing the allergic animals with increasing and ultimately massive doses of tuberculin. The general procedure of these workers was to inoculate a number of guinea-pigs with the R₁ strain of tubercle bacillus, which set up a mild and non-progressive type of infection; to leave them till skin hypersensitiveness had become well established; to divide them then into two groups; and to desensitize one group with tuberculin, leaving the other allergic. Both groups were subsequently inoculated, along with a control group of non-tuberculous animals, with virulent tubercle bacilli, and their behaviour studied. This experiment, though performed on a fairly large scale, was unsatisfactory in many respects, mainly because the mortality from intercurrent disease was so high that insufficient animals survived to allow really comparable figures to be obtained. It was found, however, that by continued inoculation of tuberculin after infection, daily doses of 2,000 mg. being given subcutaneously, the animals could be kept in a desensitized condition, and evidence was obtained that these desensitized animals were just as resistant as the non-desensitized group. The argument is therefore that immunity is independent of allergy. This method of experiment is open to serious criticism. It is surely unjustifiable to assume that animals whose

¹ Bull. Johns Hopkins Hosp., 1934, liv, 232.

antibodies are being continuously neutralized with massive doses of antigen are no longer allergic. It would be almost as justifiable to assume that an anaesthetized man who was being continuously given whiffs of chloroform was dead because he showed no signs of resuming activity. If it is to be shown that allergy and immunity are entirely dissociated some better type of experiment must be devised.

More illuminating are the results described by H. Sewall, E. de Savitsch, and C. P. Butler,¹ who, by superinfecting guinea-pigs at varying times after the first infection, obtained evidence that immunity was more or less inversely proportional to the degree of skin hypersensitiveness. Animals superinfected after seventy-four days were apparently more resistant than those superinfected after fifty-three days, the former group of animals having a rather lower degree of allergy than the latter. These results suggest that allergy gradually passes into immunity. If this conception is true, it explains why allergy may be present without any marked increase in resistance to infection, and why immunity may be present without any allergic manifestations.

A SYMPOSIUM ON GASTRIC BLEEDING

Two years ago E. Meulengracht² started feeding up instead of starving his patients with haematemesis and melaena, after noticing that some died exhausted after the old-fashioned treatment had been carried through most conscientiously, and that persistent haemorrhage was apt to cease as soon as food was given. These and other observations made him ask why a patient suffering from shock after haemorrhage should precisely at this stage be robbed of calories and vitamins whose withdrawal could hardly be expected to promote the processes of healing. Between July, 1931, and August, 1933, he let the 119 patients treated for haematemesis and melaena at his hospital eat as much as they liked. What he calls a *puré* diet was supplemented by a teaspoonful of an alkaline powder with hyoscyamus, and 7 grains of iron lactate, thrice a day. Tea and bread-and-butter were given at 6 a.m., oatmeal porridge with milk and bread-and-butter at 9 a.m., and at 1 o'clock a dinner which might include several items of an imposingly long and varied menu on which meat, fish, eggs, vegetables, and fruit were presented. Cocoa was served at 3 p.m., and sandwiches with tea at 6 p.m. Of the five deaths among these 119 cases, two were associated with cancer of the stomach and one with Banti's disease. Only two deaths were traceable to the haemorrhage itself, and in one of these cases the 50-year-old patient was already moribund when admitted to hospital. The surviving 114 patients recovered with a surprising facility, and the medical and nursing staff found their patients much easier to handle. Some of them had been treated before for the same condition on the old system of starvation or semi-starvation, and were most appreciative in their comparisons. Systematic examinations of the faeces for blood showed that on the average the benzidine reaction became negative in about ten days. In 1923, 1929, and 1930 Meulen-

gracht treated seventy-five cases on the old-fashioned lines, and twelve of them ended fatally. Among the sixty-three survivors, the average time taken for the benzidine reaction to become negative was about thirteen days. T. E. Hess Thaysen³ argues that Meulengracht's dietary must entail the irrigation of the bleeding ulcer with acid gastric juice and food, some of which is acid. To arrest haemorrhage from an ulcer, he says, it is desirable: (1) to reduce the pressure in the arteries in the area involved, and (2) to make the stomach contract. The first objective is attained by absolute rest; the second by starvation, which reduces the output of acid and the circulation of the blood. Hess Thaysen refuses to be cajoled into the abandonment of treatment by starvation, observing that many a new remedy achieves wonderful successes at the outset. He also suggests that one of Meulengracht's patients, who died of perforation of an ulcer after six days' treatment, might have escaped perforation had he been starved. Oline Christensen⁴ criticizes Hess Thaysen's criticisms and refers to gastrogaphic investigations of the human stomach which she made in 1931. They showed that an empty or nearly empty stomach is alternately at rest and powerfully contracted, whereas a fairly well filled stomach is all the time relatively at rest, the continuous contraction waves being much weaker than those of the starving, empty stomach. Her gastrogaphic records of cases of juxtapyloric ulcers and pyloric gastritis have convinced her that it is a mistake to assume that a gastric ulcer will be given rest and made to heal by starving the patient. In her opinion, the maximum of rest for the stomach can be assured by giving the patient eggs in milk in quantities and at intervals which will prevent hunger pains. While she admits that there is something to be said, from the point of view of publicity, for the doctrine which encourages a patient to wipe the blood off his mouth and forthwith eat a beef steak, a safer course for the time being would be to give eggs in milk in quantities and at intervals which would prevent pain, and, from the third or fourth day, also to give fresh orange juice in sugared water. A. Faber⁵ characterizes Meulengracht's doctrine as the outcome of the craving, from which every new generation suffers, to upset the teachings of the past, preferably by paradoxes.

NUTRITIVE VALUE OF PASTEURIZED MILK

At a time when there is a growing opinion among members of the medical profession that milk cannot be recommended for human consumption in the raw state it may be apposite to ask whether children brought up on heated milk do, in fact, thrive as well as those brought up on raw milk. Two large-scale investigations have been made to answer this question. The first was carried out in Lanarkshire in 1930. For four months in certain schools 5,000 children of 5 to 12 years of age were given three-quarters of a pint of raw Grade A (T.T.) milk a day, and 5,000 children in the same schools were selected to act as a control series. In a second set of schools 5,000 children were given three-quarters of a pint of the same milk pasteurized, and another 5,000 children in the same schools were selected to act as controls. The children were measured and

⁴ *Ibid.*, January 4th, 1934, p. 14.

⁵ *Ibid.*, January 4th, 1934, p. 13.

weighed at the beginning and end of the experiment. It was found that the children receiving extra milk grew more rapidly than the controls, and that the effects of raw and of pasteurized milk were, so far as it was possible to judge, equal. Owing to criticism from certain quarters of the technical analysis of the results, all the figures were submitted to University College, London, for re-examination by an independent authority. Dr. Ethel Elderton,¹ who conducted this fresh statistical inquiry, has now come to substantially the same conclusions as those originally reached. "There is no evidence that raw milk has an advantage over pasteurized or pasteurized over raw in increasing growth when the two are directly compared on this selected material. Thus the question of the value of pasteurization turns practically on the elimination of possible sources of disease, or on determining whether cases of certain diseases are less frequent when pasteurized rather than raw milk is taken." The second investigation was undertaken in the United States of America, and was reported in 1932.² It consisted of an extensive field study of the height and weight, at ages from 10 months to 6 years, of two groups of children, one of which had consumed raw milk and the other heated milk. Altogether over 3,000 children were studied. Since the number of those who had received no heated milk at all was practically negligible, it was decided to place in the raw milk group the children who had received raw milk for more than half their lives, and in the heated milk group those who had received heated milk for more than half their lives. The results showed that the average weight of the raw milk group was 36 lb., as compared with a figure of 36.3 lb. for the children who had received heated milk. The average height in the raw milk group was 37.4 inches, and in the heated milk group 37.5. No evidence was therefore obtained to suggest that the growth-promoting capacity of heated milk, plus the supplementary diet received by the average American child, was measurably less than that of raw milk, plus the usual supplementary diet. It is of interest, however, in view of Dr. Elderton's conclusion, to notice that the children receiving mainly raw milk had apparently suffered more from diphtheria, scarlet fever, intestinal disturbances, and rickets than the children who had received heated milk only.

AMOEBC DYSENTERY

Those who read the article on amoebic dysentery in the *Journal* of April 14th (p. 672) dealing with the recent occurrence of some cases in Chicago will welcome a note³ by the distinguished director of the United States Public Health Service, Dr. G. W. McCoy, who thinks that the facts at present at the disposal of health officers do not afford sufficient basis for the drastic measures which are being put into execution. He lends his support to the orthodox point of view, and doubts if the Chicago cases have led to much spread of the infection elsewhere: he is also of the opinion that there is no clear evidence that carriers, even among food-handlers, are an important source of infection, and that there is no need for the isolation of carriers or of contacts of either clinical cases or

carriers. Perhaps, all things considered, it would not be a disadvantage from the administrative point of view to revert to the state of affairs that existed prior to the Chicago epidemic. Dr. McCoy further calls the attention of physicians to the importance of recognizing cases of dysentery and to the general necessity for personal cleanliness among food-handlers, particularly in the washing of hands after defaecation; he also warns against the contamination of drinking supplies, and announces that research is being carried on by the Public Health Service into obscure features of amoebic dysentery. That a high incidence of *Entamoeba histolytica* infections may exist under certain conditions without any definite intestinal disturbance, let alone amoebic dysentery, is well illustrated by the figures which have been given⁴ for a group of Indian children in Wyoming. It was found that 26.5 per cent. were carriers of this organism. Again, in another paper in the same journal⁵ three cases of acute intestinal disorder which occurred in one family after visiting Chicago in August, 1933, are described. Dysentery bacilli were found in all, as well as *E. histolytica*, the latter only sixty days after the onset of the acute symptoms, which were relieved by treatment with vaccine prepared from the isolated dysentery bacillus. It is evident, therefore, that much has yet to be learned concerning the many obscure features of amoebic dysentery, as the director of the United States Public Health Service has so clearly indicated.

THE "ONE-PIPE" IN ST. MARYLEBONE

Two papers on the "one-pipe" system of drainage, one of them by Dr. Charles Porter, medical officer of health for St. Marylebone, and the other by Mr. W. H. Draper, sanitary inspector for that borough, which formed part of a symposium in the autumn series of Chadwick Lectures in 1933, have been reprinted in pamphlet form from the pages of *Public Health*. We noticed Dr. Porter's contribution at the time it was made,⁶ and the action of the London County Council in amending its by-laws to permit of the installation, under conditions, of the one-pipe system, was the subject of a more recent note.⁷ There is no need to describe again, therefore, the one-pipe system and its economical advantages; it is the standard system, according to Dr. Porter, in many other countries, but has found somewhat tardy application in Great Britain. He emphasizes the part which his own borough has played in bringing about sanitary reform. Limitations of space in St. Marylebone, and the nature and construction of the modern buildings which have arisen there, have seemed to necessitate departures from by-laws relating to sanitation. A considerable proportion of the residents have always desired sanitary arrangements in advance of anything provided in the regulations, and a progressive borough council has been ready to move with the times—or in advance of the times so far as the rest of London is concerned. St. Marylebone, by the way, is the authority which, following the American plan, places the division of sanitation in the public health department under the charge of the medical officer of health, who often finds himself called upon to submit reports upon applications

¹ Elderton, Ethel M.: *Annals of Eugenics*, 1933, v. 226.

² Frank, L. C., et al.: *Public Health Reports*, Washington, 1932, xlvii, 1951.

³ *Public Health Reports*, 1934, xlix, 359.

⁴ *Journ. Amer. Med. Assoc.*, March 24th, 1934, p. 913.

⁵ *Ibid.*, March 24th, 1934, p. 916.

⁶ *British Medical Journal*, December 2nd, 1933, p. 1043.

⁷ *Ibid.*, April 7th, 1934, p. 632.

for permission to modify by-law requirements. At Broadcasting House, which is in St. Marylebone, the liberty to have completely internal closets and soil-pipes had been anticipated, with the approval of the borough council, some years before the L.C.C. made provision for such an arrangement. It is in St. Marylebone, too, that a new hotel with a phenomenal number of bedrooms has lately been erected, and here it was desired that each bedroom should be provided with a separate completely fitted bathroom. When the scheme was first mooted the picture which came to mind was of a building hidden by a forest of pipes, but a scheme along modern lines was prepared and permission granted by the borough council. Dr. Porter says that St. Marylebone seemed suddenly to erupt buildings suitable for the one-pipe system and builders anxious to introduce it. Wherever there appeared to be good grounds for acceding to requests for special treatment the borough council permitted departure from the by-laws; but he does not think that, even with the amendments and additions which the L.C.C. has now made, reform in this direction is complete. He foresees yet greater simplification and progress, and without danger to public health. In Germany a one-pipe system was adopted some time ago, and in Berlin, in buildings of all classes, but particularly in blocks of flats, soil-pipes, which act as the sole ventilators of the system, serve as the main waste-pipes as well, and receive the discharges from baths, sinks, and lavatory basins; no detrimental effect upon the Berlin population has so far been evident. Dr. Porter is not embarrassed by too great a respect for by-laws, especially in matters relating to drainage. Some day, he hopes, the possibility will occur to all and sundry, following at a distance the confident strides of St. Marylebone, of so dealing with by-laws that they become less obstructive of progress in sanitary matters. Mr. W. H. Draper's contribution is also interesting as dealing with the more technical aspects of one-pipe construction.

LINKS WITH LISTER

Mr. C. J. S. Thompson has written a small and handy volume entitled *Lord Lister*,¹ which conveys to the reader in small space an adequate idea of the life and work of its eponymous hero. As the technical parts of the subject are treated in popular language there should be no difficulty in the way of its being understood. At the same time, the reader is put in possession of all that it is necessary to know in order to appreciate the greatness of the man and the world-wide and undying importance of his achievements. When the book comes to be reprinted, as probably it soon will be, in a new edition, no doubt the names of von Graefe, Timothy Holmes, William MacCormac, and Sir William (not Edward) Jenner will be correctly quoted. The comparatively slow acceptance of the Listerian gospel is well illustrated in some manuscript notes of lectures to nurses, which Dr. G. Francis Smith, late of Carlisle and now of Folkestone, has been so obliging as to show us. Lister's first experience with compound fracture occurred in 1865, and in the succeeding twenty years he published several notable papers on the subject of antiseptics. Nevertheless in

1885, when Dr. Francis Smith delivered his lectures, he was still not quite convinced by antiseptic doctrine, and laid more stress on "cleanliness" than on the exclusion of pathogenic organisms. Yet Koch's discovery of the *Bacillus tuberculosis* was already three years old, and the principles of bacteriology well established. Dr. Francis Smith rightly instructed his nurses that the greatest principle of all is cleanliness, and he pointed out the danger of contamination of wounds from the carelessness of assistants, nurses, and others who had not grasped the principles of the antiseptic or aseptic methods. Many of the senior surgeons were too old to learn, and it was not till younger men came into the control of wards and theatres that Listerism got a fair chance.

WELFARE OF THE BLIND

In 1927 the Ministry of Health published a most useful handbook on the welfare of the blind in England and Wales²: this has now been issued in revised form. The aim of the work is not to stimulate interest on behalf of the blind, for that is assumed to exist; it is to supply those interested with the facts relating to blindness and the assistance of the blind, so that they may be able to take an intelligent part in any work they do for the blind. The handbook is a necessity to every ophthalmic surgeon, medical officer of health, and school medical officer, and it would be of value to many social workers. Since 1927 there have been many changes, chiefly due to the Local Government Act of 1929 and the consequent altered relation of the statutory authorities to the blind societies. The latter now have no direct access to the Ministry, but come under the local authorities. This change has considerably modified methods whereby the blind may be helped, so that a new handbook was greatly needed. Attention is drawn to the statutory definition of blindness and the explanation thereof suggested for the help of those who have to use that measure. It is truly stated that certification of blindness is often a difficult matter, and consequently the Minister has indicated that it was

"desirable to make arrangements for securing that before a person's name is added to the register he is examined by a medical practitioner with *special experience in ophthalmology*. It appears to the Minister that the necessary expenditure for this would be clearly justified by the consequent avoidance of registration of persons who are not blind within the meaning of the Blind Persons Act, and the saving of expenditure which might otherwise have been incurred in respect of such persons."

The latest returns of the numbers of blind persons on the registers on March 31st, 1932, were 62,079, and on the same date in 1929 52,727. The increase is believed to be due mainly to the improvement of the machinery for registration. But it may also to some extent be the result of the substantial benefits now available to the blind, and to the consequent inducement for persons (some of whom may not be blind within the meaning of the Blind Persons Act) who were not previously registered to apply for and obtain registration as blind persons. This consideration reinforces what has been said on the great importance of the proper certification of blindness. Over 77.3 per cent. of the total number

¹ *Handbook on the Welfare of the Blind in England and Wales*. Revised edition. London: H.M. Stationery Office, 1934. (1s. net.)

² *Lord Lister, The Discoverer of Antiseptic Surgery*. By C. J. S. Thompson, M.B.E. London: J. Bale, Sons and Danielsson, Ltd. 1934. (Pp. 19. 5s. net.)

of the blind are classed as unemployable. This is explained when the age factor is taken into consideration, for seven out of every ten are over 50 years of age. There has been a material diminution of the number of blind children owing to the prevention of ophthalmia neonatorum; consequently the increase in the proportion of blindness in the higher ages of life, when the possibility of work is small, becomes evident. The unemployed blind fall into two categories—those who are capable of being employed and those who are not. It is important to distinguish between them, for there is provision in all schemes for aid in training anyone who is capable of being trained and usefully employed. Nearly 87 per cent. of the blind between 50 and 70 are in receipt of old age pensions. Formerly institutions for the blind were a necessity for many; now, when incomes are made up to one pound a week or more, it becomes possible and better for them to live at home or with friends. It is more desirable for the blind to be members of a sighted household if they are properly cared for. The new handbook deals with the varied needs of the blind, and indicates what means there are for putting them into as satisfactory a position as their capabilities will allow. The section on the prevention of blindness should be read by all employers of labour, for loss of sight due to accident is a material factor in adding to the tale of the blind.

THE DANGERS OF CARBON BISULPHIDE

Carbon bisulphide is used in various industries, such as the manufacture of artificial silk and rubber goods, and it is very dangerous because of its poisonous and volatile nature. The Factory Department of the Home Office has therefore issued a memorandum¹ explaining the precautions which should be taken in order to minimize the risks of poisoning, fire, and explosion. It points out that the vapour of carbon bisulphide is toxic even in low concentrations, and has a profound effect on the nervous system. A concentration of about 600 parts per million produces serious disturbance if inhaled for an hour, whilst double this concentration is dangerous in thirty minutes. The usual effects in workers exposed to the vapour are nausea, indigestion, headache, and giddiness, sometimes accompanied by emotional disturbances of a hysterical character. With continued exposure the mental disturbance increases, and is accompanied by impairment of memory and mental depression. There may be muscular weakness due to toxic neuritis, especially of the facial muscles and flexor muscles of the forearms, and ultimately the affected person may become almost completely paralysed. Slow recovery usually takes place after removal from the toxic vapour, but in advanced cases permanent effects may remain. Cases of industrial carbon bisulphide poisoning have to be notified to the Factory Department, and since 1925 they have numbered only eighteen in all, but they might easily increase unless the suggested precautions are taken. These consist of efficient exhaust ventilation, and periodical transference of the exposed workers to other processes where carbon bisulphide is not employed.

Nova et Vetera

A HISTORY OF NURSING

Pride in one's art or craft must be connected with the consciousness that it is good work, but there may be added to this a pride that one is doing work that has a long and honourable history behind it. For the nurse there is this double pride. In addition, she may be proud of the great advance made in nursing within known memory. A *General History of Nursing*,¹ by Miss Seymer, might well be a treasured possession of every nurse, for therein is told, and told most effectively, the history and recent growth of nursing services.

Ancient India has the honour of possessing the earliest certain record of a nursing service. In the *Sushruta-Samhita*, dating from about the fourth century B.C., there is evidence that each village had its doctors and hospitals. There is this remarkable passage:

"That person alone is fit to nurse or to attend the bedside of a patient who is cool-headed and pleasant in demeanour, does not speak ill of anybody, is strong and attentive to the requirements of the sick, and strictly and indefatigably follows the instructions of the physician."

It has never been satisfactorily explained how this great Hindu civilization met such swift and complete decay; conquest by less civilized peoples may be held accountable. Much earlier records than this suggest that nursing was done, probably by members of the household. The Egyptians in the temples of Imhotep practised incubation; this implies attendants. The public health laws of the Jews were strict on the hygiene of women after childbirth, and on the diagnosis, quarantine, and cleansing of leprosy. Houses for strangers were provided, but whether they were inns or hospitals is a moot point. There is evidence that in early Greece there was a practice of medicine other than by the priesthood. Homer describes the doctor as "a man worth many others," and the fair-haired Agamemnon knew as many drugs as the wide-earth nourishes. We are bound to assume, however, from the absence of all records to the contrary, that in Hellenic and Hellenistic times real nursing by efficient women was practically unknown. Rome developed a system of military hospitals; Vegetius, late fourth century A.D., gives an account of the organization of these soldiers' hospitals, and speaks of the prefect of the camp as being in charge of the "sick who are in tents and the doctors by whom they are healed." But there does not appear to have been any public hospital where the poor were treated until Christian times, for St. Jerome says that Fabiola built the first hospital in Rome. Early records describe women "deaconesses," who seem to have served as nurses. Certainly they are referred to in the third century as "assisting the women visited with sickness."

EARLY NURSING ORDERS

The first Christian hospitals combined hostel, infirmary, and orphanage, for the sick, the old, and the destitute were gathered there. With the growth of, and gradual control by, the monastic orders these infirmaries became ecclesiastical rather than medical; care rather than cure became their aim. There were nursing orders, such as the Knight Hospitaliers, the Teutonic Knights, and the Lazarists; in the second of these there were lay sisters, who were admitted "because services to cattle and to sick persons in hospital are better performed by the female sex." With the Reformation such hospitals as survived came under the control of laymen—St. Bartholomew's, St. Thomas's, Bridewell, and others in England, and the Hôtel-Dieu in Paris. Early in the seventeenth century St. Vincent de Paul founded that famous nursing order known as the Sisters of Charity. The sisters had on no account to be called "religious"; in this St. Vincent ran counter to all the traditions of the Roman Church. He said:

¹ A *General History of Nursing*. By Lucy Ridgely Seymer. M.A. Oxon., S.R.N. London: Faber and Faber, Ltd. (12s. 6d. net.)

"The Sisters of Charity shall have for monastery the houses of the sick, for chapel the parish church, for cell a hired room, for cloisters obedience, for grille the fear of God, and for veil holy modesty."

From the end of the seventeenth century to the middle of the nineteenth little or no progress was made in the art of nursing; in some places there was actual deterioration. In England, at the time of the Great Plague, the so-called nurses were "dirty, ugly, unwholesome hags." Even in European countries the religious sisters, despite their discipline and devotion, were, as science advanced, increasingly hampered by antiquated routine.

Although there was much hospital building in England in the eighteenth century the nursing was mean. Sometimes the qualification of the nurse chosen was merely that she had been a patient. In America the "nurses" were "ten-day" women detailed from the penitentiary. A faint desire to remedy bad conditions by better pay appears in the records of the Middlesex Hospital, London, in 1838:

"The committee are, however, of opinion that a hope may be entertained by raising the wages . . . of procuring and retaining the better description of nurses—women who will take more interest in their duties, their character, and appearance."

One of the most important factors in the regeneration of nursing was the Deaconess Institution at Kaiserswerth, set up by Pastor Theodor Fliedner. In 1836 he revived the ancient order of church deaconesses. Elizabeth Fry paid a visit to Kaiserswerth in 1840, and in recording the visit her niece wrote:

"Pastor Fliedner . . . has also instituted Protestant Sisters of Charity whom he terms Deaconesses. They are all dressed alike in blue print gowns and neat white caps. They wait entirely on the patients, go out to visit the poor, and are sent to any parts of the Kingdom."

NINETEENTH CENTURY REFORMS

About this time the need for nursing reform attracted the attention of far-sighted women in England, Ireland, and Germany, and several "sisterhoods," both lay and clerical, were founded. Some of these took over the nursing services of large London hospitals. Impetus was given to the movement by the vivid pen of Charles Dickens, whose portraits of "Mrs. Sairey Gamp" and "Mrs. Betsy Prig" depict the depths to which the ordinary professional nurse had sunk. Of all these nineteenth century attempts to improve nursing the most original is the foundation, one year before the Nightingale School, of "La Source," at Lausanne, by the Comtesse Agénor de Gasparin. She founded this institution as a protest against the "motherhouse" system, which she felt to be definitely wrong. Her opposition to it was based on two main principles: first, that the personal liberty of each individual was of paramount importance; and, secondly, that women should be salaried, and not bound by vows. She called it a training school because she thought piety was not enough, and students should be systematically and thoroughly trained by doctors.

The work of Florence Nightingale is too well known to need elaboration. It is certain that she early had a personal bent for nursing, and this was stimulated by visits to hospitals abroad, and particularly by a visit to Kaiserswerth. Her first undertaking was the superintendence of the "Establishment for Gentlewomen during Illness" at 1, Upper Harley Street. She was there a full year, broken by holidays and a short term of service at the Middlesex Hospital during a cholera epidemic. The Crimean war gave Florence Nightingale her opportunity. She and Sidney Herbert, then Secretary at War, encouraged by an awakened spirit at home, as evidenced by "The Times Fund," rode roughshod over military red tape. To have women nurses with the British Army! It was immodest, unthinkable, revolutionary! And yet this was the epoch-making idea that Sidney Herbert not only suggested, but carried into effect. If Florence Nightingale was the foundress of modern nursing, Sidney Herbert must rank as its patron.

THE NEED OF TRAINING

In the general field what differentiated Florence Nightingale's ideas from the opinions of her contemporaries was her insistence on the necessity of training for work. She said.

"Three-quarters of the whole mischief in women's lives arises from their excepting themselves from the rules of training considered needful for men." And again: "An uneducated man who practises physic is justly called a quack, perhaps an impostor. Why are not uneducated nurses called quacks and impostors? Simply I suppose because there are few who think a man can understand medicine and surgery by instinct. But till the last ten or twenty years people in England thought that every woman was a nurse by instinct."

With appropriate training the nurse has become a professional woman—competent, trustworthy, and highly valued. The wide range of her services can be judged by the several chapters of this book which deal with the Red Cross, the growth of training schools, and public health nursing, including maternity and child welfare. There are useful accounts of State registration systems throughout the world, of insurance and pension schemes for nurses, of nursing journals, and of organizations that are maintained by nurses for the honour and interest of their profession. Miss Seymour appends a useful bibliography, and there are some thirty-seven illustrations of great general interest.

FORTHCOMING ANTHROPOLOGICAL CONGRESS

Last year, at a meeting at Basel, convened by the Royal Anthropological Institute of Great Britain, it was agreed by representatives of anthropology and ethnology from nine countries to establish an international congress on these sciences and to hold a session every four years, the first to be in London in 1934. Accordingly the congress is to meet at University College, London, and the neighbouring Wellcome Historical Medical Museum during the week beginning July 30th. At the inaugural meeting the Duke of York will welcome the delegates of Governments, academies, universities, and other societies and institutions, and the Earl of Onslow, the president of the congress, will deliver an address.

The main work will be done in eight sections, each with a British chairman. The section of anatomy and physical anthropology will be presided over by Professor G. Elliot Smith, that of psychology by Professor F. C. Bartlett, and that of demography and population problems by Professor C. B. Fawcett. The other sections deal with ethnography, African and American, arts and crafts, sociology, religions, and language and writing. An ambitious programme is mapped out for the five or six meetings of the section of anatomy and physical anthropology, whose central theme will be man's place among the primates. The principal subjects will be anthropological aspects of blood grouping, human and comparative; the comparative anatomy of the brain; diathesis or bodily habits in relation to physical anthropometry, including a survey of asthmatic and rheumatic children and a study of racial features in the growth of the jaws; the growth pattern in children, with special reference to the skeletal, neural, lymphoid, and urogenital systems; special work on the role of the endocrines in growth; the study of sex and behaviour, including the menstrual cycle in man and primates and also lactation; various aspects of dentition; the localization of function, and the standardization of methods of measurements. Some of the subjects, such as regional anthropology and fossil anthropology, may be discussed in subsections. The section of psychology will consider the aims and methods of social psychology, psychological problems arising from contact of races, in particular the nervous strain and reactions arising from the impact of alien cultures, the social significance of modern developments in psychology, such as the application of psychological tests, and the significance of present-day trends in government, education, and physical and biological sciences. The section

or demography is to discuss the methods and technique of census-taking, also the relations of racial characteristics to internal distributions within populations, such characteristics, for example, as eye colour and visual acuity, physical race characters and occupations, and race and caste. The section of languages and writing includes in its programme the study of the use of speech and voice mechanism among different races, speech pathology, psychological evidence bearing on the existence of the word as a separate entity, the development of speech habits among children, and the difference between the motor and the auditory aspects of speech.

In addition to the sectional discussions there are to be a number of evening discourses, including a Huxley Memorial Lecture by Sir Aurel Stein, the great authority on Indian and Central Asian archaeology, and a discourse by Professor J. B. S. Haldane on the growth and tendency of anthropological and ethnological studies. A reception is to be given by the Government at Lancaster House, by the Royal College of Surgeons at Lincoln's Inn Fields, and by various museum authorities, and in the week following the congress visits will be paid to Oxford and Cambridge and to certain provincial cities. The list of vice-presidents includes the names of Sir Arthur Keith, Sir Humphry Rolleston, and the presidents of the various societies which touch on the subjects coming before the congress.

It should be made plain that the new congress will always meet at two years' interval between the international congress of prehistoric and protohistoric sciences, which was held first in London in 1932, and meets again at Oslo in 1936. The congress has also been arranged so that its meetings will fall in the same years as the Americanist Congress in Europe. That congress meets in Seville later in the present year, and it is hoped that workers in the American field may be able to attend both. The forthcoming event in London is being organized from the offices of the Royal Anthropological Institute, at 52, Upper Bedford Place, W.C.

THE BRITISH RED CROSS IN PEACE

The activities of the British Red Cross Society, as recorded in the annual report for 1933,¹ show continued growth in all departments. The number of voluntary aid detachments reached a total of 831, with a personnel of 21,486 members. The first two air ambulance detachments were registered in 1933. Reference has lately been made in these columns to the work of the Society's clinic for rheumatism, where 94,256 attendances were made last year, as against 86,929 in 1932, and the range of treatment and investigation has been widened. The blood transfusion service received the record number of 3,017 calls in the London area—an increase of 575 over the previous year; the number of donors on the roll is now 1,536.

The junior branch of the Society now numbers 370 "links," with a total membership of over 25,000 boys and girls. The usefulness of this movement as an educational instrument is increasingly recognized, while the senior branch benefits by the accession of numbers of young people brought up in sympathy with the traditions and ideals of the Red Cross.

The county branches of the Society have continued to develop their voluntary services to the public. They have provided 374 first-aid posts and patrols on the roads and sea beaches, and 603 emergency first-aid stations at large gatherings. Assistance is also given at hospitals, clinics, and welfare centres. Medical supply depots for the loan of surgical and nursing equipment to necessitous cases are established throughout the country, and now number 109.

The fifth Congress of French-Speaking Dermatologists and Syphiligraphers will be held at Lyons from July 19th to 21st of this year, under the presidency of Professor Nicolas of Lyons, when the exclusive subjects for discussion will be the etiology and treatment of lupus erythematosus, diagnosis of chancreoid bubo, and cutaneous complications of anti-syphilitic treatment. The membership subscription is 150 francs, which should be sent to the secretary of the Congress, 24 Rue Saint Hélène, Lyons.

Reports of Societies

RELATION OF MORTALITY TO HOUSING DENSITY

At a meeting of the Section of Epidemiology and State Medicine of the Royal Society of Medicine, held on May 25th, Dr. J. D. ROLLESTON presiding, a paper was read by Dr. PERCY STOCKS, medical statistical officer of the General Register Office, on "The Association between Mortality and Density of Housing."

Dr. Stocks, whose paper was largely occupied with tables and graphs, and a description of his statistical method, first compared the relation of child mortality to density per acre in a period before the Public Health Act (1861-70) with that for 1930-2, taking groups of urban and rural districts and county boroughs. At densities of less than one person per acre, into which category fell most rural aggregates, the present mortality rate for ages 0 to 5 was only 29 per cent. of what it was in the earlier period, and at a higher density—namely, five to ten per acre—comprising the present urban districts in the main, the relative mortality was lower still, being only 20 per cent. of the early figure. The crowding of houses together up to an average density of ten persons per acre had no apparent effect on the mortality of children, but in densities of over twenty per acre—that is, in most of the present county boroughs—there was the same relative excess in child mortality as compared with less dense populations which was apparent sixty-five years ago, although, of course, the actual mortality in dense and less dense areas alike had greatly diminished.

It had often been stated that the mortality risk increased with movement northwards in each class of area, the implication being that this was due to colder climate, more smoke, more occupations dangerous to health, or a combination of these. But if Great Britain were divided into successive zones of latitude (omitting London, the case of which must be separately considered), it would be found that, moving northwards, there was a progressive increase in the mean density per room until the Scottish industrial area was reached, while the density per acre was at its highest level in the zone which included the industrial area of Yorkshire and Lancashire, and then steadily declined on passing further north. The behaviour of the mortality rate for children under 5 bore a much closer resemblance to the trend of average density per room than to the trend of density per acre. The well-known north-to-south gradation of mortality rates seemed likely to arise from the gradation of overcrowding within the houses, and climatic differences between the latitudes had little effect on mortality. Dr. Stocks had set himself to disentangle the relations of mortality to the three factors of latitude, urbanization, and crowding within houses. The fact was established, he said, from a number of researches that within a given town the mortality risk, particularly in early childhood, was greater for occupants of more crowded houses than for occupants of less crowded ones, but this had been variously attributed to the direct effects of crowding, unfavourable industrial conditions associated with crowded areas, the poverty of which crowding was often a symptom, or the gravitation of the less fit into unsatisfactory conditions of housing, so that it was little wonder if the advantages predicted from housing improvement *per se* ranged from the utmost optimism to the utmost pessimism. The broad conclusion to be drawn from his own figures was that at ages over 5 it was not necessary to suppose that mortality from all causes combined was appreciably affected by climatic differences dependent on latitude within the limits of England and Wales, and probably Great Britain. The mortality of children under 5 from respiratory disease showed an increase on passing from the South Coast to the industrial North of England amounting to 42 per cent., even after allowance had been made for the effects of increasing density and of crowding per room, but there was a decline in this respect on passing still further north. Dr. Stocks's curves also brought out the advantage in respect of sunshine in the eastern part of England (except at a latitude which included the industrial area of

Yorkshire, where the effect of the smoke blanket from industrial towns to the west was observed), but apart from the effect of diminished sunshine in predisposing to rickets, which in its turn contributed heavily to bronchitis and pneumonia in young children and lowered resistance to infectious diseases, he was not convinced that there was any real evidence that the differences in average mortality experience between different parts of Great Britain had anything to do with climate.

Dr. Stocks also set himself to determine whether, with improved sanitation of towns, the crowding of people within their houses had assumed a greater importance in association with mortality than the crowding of houses together. London mortality was uniformly lower than that of the rest of England and Wales when districts of the same density per acre were compared, and this was also true, although the advantage was not so great, when districts of the same density per room were compared. The advantage of London, so far as mortality at ages under 5 was concerned, must derive partly from its southern situation, with consequent greater amount of annual sunshine. At ages over 5, although the climatic factor seemed to be unimportant, yet for some reason London again had in general an advantage, amounting to between one-fifth and one-third, over other parts of the country of the same density per acre or per room. At ages over 45, however, this advantage became less perceptible. Dr. Stocks confessed himself unable to explain the advantage of London. Was the greater triumph over environment by people living in the metropolis due to selective migration of the healthiest young adults to London, to a greater immunity against certain diseases afforded by living in the middle of a vast herd, to the better protection from the rigors of winter afforded by London amenities, to better facilities for medical treatment and more advanced public health, or to all of these? In the metropolitan boroughs infant mortality from congenital causes had no association with either measure of density, but from other causes the rate showed an increase at densities of over fifty per acre, and rose with increasing density per room. At school ages there was little relation with density per acre, but the rate rose with crowding from 0.92 persons per room upwards. For women the death rates from phthisis were actually highest at low densities per acre, but increased with room crowding. At later ages for all persons the effect of density seemed slight, and at ages over 65 scarcely appreciable. In England and Wales, excluding London, the corrected ratio for infant mortality from congenital causes showed, as in London, no association with density per acre, but rose with crowding per room. At school age densities of over thirty per acre had slightly higher rates, but the rise in the rate was more pronounced with crowding per room; and, again, at the other end of life, the effect of density by either measure was slight.

Dr. Stocks's general conclusion was that up to middle life the importance of crowding per room as a factor in mortality was now almost double that of density per acre. The results of overcrowding were far and away most serious at the pre-school ages, and it was here that the greatest benefits might be expected as a result of housing improvements in the future.

GENERAL DISCUSSION

Sir WILLIAM HAMER mentioned that, three-quarters of a century ago, William Farr made the confident statement that large towns would never become so healthy as the country, but that prophecy had not been borne out. One possible cause for the marked decline in infant mortality since the early part of the present century was the Education Act, 1870, which meant the appearance in due time of a generation of mothers who had passed through the elementary schools and were able to take a more intelligent interest in the welfare of their children.

Professor MYJOR GREENWOOD said that, apart from his digression with regard to the special effects of diminished sunshine, Dr. Stocks's general thesis was that for practical purposes mortality was not in this country a function of climate. He himself remembered trying this out many years ago, the special subject being the mortality from respiratory diseases. The incidence of pneumonia and

bronchitis was found to be enormously high in the North of England, but taking the figures for 1901-10, and the deaths from these diseases at ages 65-75, while the rate for England and Wales as a whole was 7.4 per 1,000 living, and that for Lancashire 12.6, the rate for the contiguous counties of Cumberland and Westmorland, where the same climatic influences operated, was only 4.8. This was completely explained by the great difference in housing density, but it illustrated the negligibility of the climatic factor.

Dr. J. D. ROLLESTON mentioned that he had recently received a work by Professor Robert Debré, a member of the League of Nations Committee of Health Experts on *Infant Welfare in Europe*, in which, with two colleagues, he had made a study of infant mortality in France and some other European countries, in urban and country districts. One of his most important conclusions was that the outstanding factor in infant mortality was the density per room and the various unhygienic conditions associated therewith. That was particularly well shown in a working class district of Paris, where, in spite of progress in other respects, living conditions in rooms were really deplorable. Dr. F. C. SHUTTSALL suggested that the true criterion was the hours of ventilation. In London tenements young children on the higher floors, though they got more fresh air in their rooms, were often kept in, whereas those on the ground floor were turned out, so that the latter, although they might have a worse time at night, enjoyed more hours of sunshine and ventilation during the day. Dr. E. W. GOODALL asked some questions with regard to the relation of mortality from measles and whooping-cough to housing density.

Dr. Stocks, in reply, said that the relations of whooping-cough mortality to crowding were rather complex. Whooping-cough seemed to differ in this respect from measles, and he did not think that case mortality would necessarily follow the same rules as the actual mortality per 1,000 children in parts densely and not densely populated respectively.

RECENT WORK ON LEPTOSPIROSIS (WEIL'S DISEASE)

At a meeting of the Royal Society of Tropical Medicine and Hygiene, held at Manson House on May 17th, with the president, Sir LEONARD ROGERS, in the chair, Professor W. SCHÜFFNER read a paper on recent work on leptospirosis.

In his introductory remarks Professor Schüffner said that Holland enjoyed the doubtful privilege of harbouring two diseases which in other countries were supposed to be rare. One was post-vaccinal encephalitis, claiming numerous victims among children, the other was Weil's disease, or leptospirosis, which had come to the fore during the past ten or twelve years both in Holland and in her East Indian colonies. The incidence in Holland was greatest in the western coastal part of the country—an area situated below sea-level and much of it covered with water. Of 234 patients diagnosed in his own laboratory twenty-seven had died, giving a case fatality of 11.5 per cent., but fortunately the total number of deaths was small, only sixteen patients dying in 1932 and eleven in 1933 in Holland. Cases occurred throughout the whole year, but epidemic exacerbation appeared from July to October. Forty-five per cent. of the adult sewer rats in Holland carried leptospirae, and there were certain occupations (such as bargemen, fishermen, and slaughterhouse employees) in which the incidence was higher. "Water accidents" definitely predisposed, and here the lecturer had found that canal water polluted with refuse where the banks teemed with rats was particularly dangerous because of its leptospiral content. It had been found that guinea-pigs immersed in such water occasionally acquire the disease, provided the skin be slightly scarified, but culture of the leptospirae from naturally infected water had not been successful. The mucous membranes were probably also important avenues of infection, and diving, and swimming by the crawl stroke, enhanced this risk. The pH and salinity of infected water were important factors controlling the growth of leptospirae. The average incubation period

equalled 10.3 days, and a history of a "water accident" in the previous week or two was an important factor in the diagnosis; the alarming symptoms at onset also helped. Often there were distressing muscular pains, a heavily furred tongue, a leucocytosis with shift to the left, albuminuria, meningeal symptoms, and peculiar flushed conjunctivae or "red eyes." The latter feature was present in half of the cases of Weil's disease occurring without icterus, and under such circumstances the diagnosis was exceedingly difficult and needed confirmation in the laboratory. No such cases were ever fatal.

For brevity Professor Schüffner omitted further reference to the clinical diagnosis, but pointed out that the final decision of Weil's or no Weil's disease rested with the bacteriologist, whose diagnosis was based on (a) demonstration of leptospirae in the blood, (b) cultivation, (c) serological reactions. Leptospirae were readily demonstrated in the blood of infected guinea-pigs by dark-ground illumination, but this procedure was rarely successful in man. Centrifugalization was often of value, provided the plasma be separated from the precipitated corpuscles and examined in a thick layer. Before direct cultivation of blood for leptospirae preliminary passage through a guinea-pig was desirable. The coagulum should be triturated and injected into the peritoneal cavity, where the leptospirae might be detected as early as the third day. Leptospirae were most commonly isolated from the blood during the first three or four days of the disease, but in severe cases they might persist until the tenth day; examination of the urine was sometimes successful in the later stages, long after leptospirae had disappeared from the peripheral circulation. Agglutination tests were best carried out by formalized cultures of leptospirae, since such extracts were not dangerous to handle, they constituted potent antigens, and lysis of leptospirae, such as was sometimes encountered with living cultures, was avoided. After formalization "matting" of leptospirae due to acid agglutination sometimes occurred, but this could be prevented by using 1/2 per cent. instead of 2 per cent. formalin. Absorption tests could also be applied, thereby distinguishing between specific and cross agglutination. Clinical, serological, and epidemiological facts combined to show that there were three European leptospirae: (1) the cosmopolitan *Leptospira icterohaemorrhagiae* in rat and dog, the cause of classical Weil's disease; (2) *L. grippotyphosa*, the infecting agent of swamp fever in Europe, the reservoir host of which is unknown; (3) *L. canicola*, causing a specific canine disease.

GENERAL DISCUSSION

Dr. W. FLETCHER commented on the fact that 40 per cent. of cases of leptospirosis in Holland were of mild type unassociated with jaundice; in the Malay States the percentage with jaundice was even less. There he and his colleagues had found six different races of leptospirae classified by means of agglutination tests and by Pfeiffer reactions in young pigs. Guinea-pigs, however, which had recovered from infection with one strain had a considerable immunity to infection with other races. He suggested that the leptospirae of Holland might have resulted from the importation of strains from the Orient. Dr. E. HINDLE was not prepared to accept serological strains as distinct species, because of the overlap in serological reactions. In conjunction with Dr. Bruce White he had recently been able to isolate a specific soluble substance from spirochaetes which gave a precipitate with high dilutions of antiserum derived from animals infected with homologous spirochaetes. While there were many different water strains, the various human and rat strains all reacted to specific soluble substances isolated from rat strains, which included one from Malay. Major BROWN referred to results obtained by the adhesion test, which consisted of putting up serum, leptospirae, and a suspension of micro-organisms; if the serum was specific the bacteria would adhere to the leptospirae. By means of this reaction he had no difficulty in separating *hebdomidis* from *icterohaemorrhagiae* or from the water strains. Regarding acid agglutination in formalized cultures, he wondered whether the neutralization of formalin by pyridin, as recently recommended by Burke,

would be of help. From a clinical viewpoint "red eyes" could not be considered pathognomonic of leptospirosis; he had noted it with great frequency in other forms of epidemic jaundice.

Dr. FINDLAY referred to epidemics of jaundice in England, Norway, and Sweden, where leptospirae were absent; these were sometimes associated with subacute yellow atrophy of the liver, and occasionally terminated in cirrhosis. He asked whether any patients with Weil's disease who had not shown jaundice had died with these complications. Dr. C. M. WENYON referred to the early observations made by Brown and himself indicating the identity of *Leptospira icteroides* with *L. icterohaemorrhagiae*, and asked Professor Schüffner about the leptospiral haemoglobinuria which he had described in Sumatra.

Dr. MANSON-BAHR referred to the difficulty of diagnosis now that clinicians had to recognize Weil's disease without jaundice, and were no longer able to regard "pink eyes" as pathognomonic of leptospirosis. Since his discovery of the disease in London in 1922 he had never met a case. He asked for more information regarding the use of antileptospiral serum in Holland. Dr. PARISH spoke on the subject of active immunization, and asked if a vaccine prepared against the true virus strain protected animals against the curious dog strains which Professor Schüffner had described. Professor WARRINGTON YORKE discussed the dangers of differentiating species merely on serological grounds, illustrating his remarks with reference to trypanosomes.

In reply, Professor SCHÜFFNER reviewed the evidence whereby the three different European strains were differentiated, and confirmed that there was a form of haemoglobinuria associated with leptospirosis; slides of microscopical sections were then shown, demonstrating leptospirae in the kidneys of such cases. Regarding specific serum treatment, he cited a case of a laboratory-acquired infection in which leptospirae were found in the blood after the first few hours of illness; five hours from onset serum therapy was instituted, with remarkably satisfactory results.

TROPICAL MACROCYTIC ANAEMIA

At a meeting of the London Association of the Medical Women's Federation, held at B.M.A. House on May 22nd, Dr. LUCY WILLS spoke on tropical macrocytic anaemia.

Dr. Wills gave an account of her work on this subject during the last five years. In 1928 this condition was described in pregnant women under the title "pernicious anaemia of pregnancy," and was a serious cause of maternal and foetal mortality in the large cities of India. The blood picture resembled that of true pernicious anaemia, but the condition could be distinguished from idiopathic pernicious anaemia by the following characteristics: (1) earlier age incidence and the association with pregnancy; (2) absence of natural remissions except after delivery; (3) the presence of free hydrochloric acid in normal amounts in the gastric content of the majority of cases; (4) absence of a raised indirect van den Bergh reaction, or an increase in urinary urobilin; (5) absence of nervous involvement; and (6) slight differences in the blood picture—for example, less poikilocytosis and polychromasia and higher white cell counts. The cases were frequently febrile, but no evidence could be obtained of an infective or toxic origin. The general course of the disease and the response to adequate doses of liver or liver extracts suggested a nutritional origin. Further study showed that an identical form of anaemia also occurred among men and non-pregnant women, which also supported the view that the disease was a deficiency state, the higher incidence and the greater severity in pregnant women being due to the added demands on the organism during pregnancy. A dietetic survey among the hospital classes in Bombay revealed a deplorable state of multiple deficiencies, with no significant difference in the diet of sufferers from this anaemia. All the diets were particularly low in vitamins A and C. Experiments with rats fed on diets based on those in common use among sufferers from this anaemia resulted in the production of a macrocytic anaemia, which, however, was

associated with the multiplication of *Bartonella* organisms in the blood stream. A search for similar organisms in the patients gave negative results, and large doses of vitamins A and C had no curative effect. Similar experiments with monkeys (*Bartonella*-free) again led to the production of a macrocytic anaemia, but in both the control animals, which were receiving additional rations of vitamins A and C, and the experimental animals, when the ration of the vitamin B complex was increased by the addition of marmite to the diet the anaemia was rapidly cured. The trial of marmite in human cases was equally successful, 15 to 30 grams of marmite daily resulting in a maximal response and a rapid rise in the red cell count in both pregnant and non-pregnant cases. At this time Castle and his co-workers were publishing their work on the factors, intrinsic and extrinsic, necessary for the formation of the haemopoietic factor in liver. As the tropical cases has apparently normal gastric secretion it was assumed that the intrinsic factor was present, but that the missing dietetic factor was Castle's extrinsic factor. After the publication by Dr. Wills of her results with marmite the Boston workers tried a similar autolysed yeast extract, and found that, though inactive alone, when incubated with normal gastric juice it was highly active in the cure of idiopathic pernicious anaemia. These workers postulated vitamin B₁₂, or some factor closely associated with it, as the extrinsic factor in pernicious anaemia.

At this time, Dr. Wills said, further work with standardized vitamin and yeast preparations in relation to tropical macrocytic anaemia had already been started by her, with the help of Miss H. Chick. For the test of these preparations uncomplicated cases under controlled conditions were used, and the activity of a preparation was judged by the height of the reticulocyte peak and the subsequent rate of blood regeneration. Vitamins B₁, B₂, and B₆ were inactive curatively when given in the purest available form—that is, as acid clay and extract of egg white, or of watery yeast extract of known vitamin potency; further, preparations of marmite free from these vitamins were still active curatively. The vitamin B complex was therefore excluded as the haemopoietic factor in marmite curative in tropical macrocytic anaemia, and also presumably as the extrinsic factor in pernicious anaemia. Further experiments showed that the haemopoietic factor in marmite was heat-stable, and was neither precipitated nor inactivated by 80 per cent. alcohol. Whole yeast was inactive, but Dr. Wills suggested that this might be due to the fact that yeast cells were resistant to gastric digestion, rather than to the absence of the haemopoietic factor. She summed up the present position as follows. Tropical macrocytic anaemia is a deficiency dyshaemopoietic anaemia due to the lack of the haemopoietic factor in the liver, known as the pernicious anaemia factor. The disease is distinct from idiopathic pernicious anaemia, and is not necessarily associated with the other causes of macrocytic anaemia—diarrhoea, defective gastric secretion, or pregnancy. The deficiency was, in her opinion, due to a dietetic lack of some substance, present in marmite, which is not one of the known B vitamins, but which is probably identical with the extrinsic factor described by Castle for idiopathic pernicious anaemia. The tropical anaemia is cured by the administration of the missing factor, as marmite, or of the pernicious anaemia factor present in liver.

Dr. HELEN MACKAY asked if there was any explanation of the absence of nervous symptoms and natural remissions, and of the fact that there was no record of the disease in children, who were normally more susceptible to deficiency diseases than adults. Dr. WILLS, in reply, said that as regards nerve changes there was possibly not time enough for these to develop in the young patients, but it seemed more likely, in view of the age of some of the non-pregnant patients, that the nerve lesions of true pernicious anaemia were associated with the gastric lesion rather than with the absence of the haemopoietic factor, which would explain the absence of nerve lesions in the tropical form. She thought that further study might show that remission did occur in exceptional cases, but had no explanation of the absence of recorded cases in children.

CORRESPONDENCE

Lister and Chemical Antiseptics

SIR.—Although far away from the close friendship of Sir Watson Cheyne and the relationship of Sir Rickman Godlee with Lord Lister, I had the privilege of being his last assistant in his private practice, and when he ceased clinical work he left private and hospital patients under my care. Consequently I often heard from his lips many of his thoughts and of the different kinds of opposition against which he had to contend in the early days of his practical application of Pasteur's discoveries to medicine and surgery.

Among other things, it does not appear to be generally known that one of Lister's sayings was that he "at once recognized that boiling water is the best antiseptic in existence," and in his earliest experiments he proved it to his own satisfaction. In spite of this fact he always maintained that it was a safer, an easier, and a more fool-proof method—as matters then stood—to keep everything connected with a wound in constant contact with a chemical antiseptic. He believed that in those days the employment of heat alone required more detailed care in its application than lotions, and also far greater experience and education in bacteriological knowledge than was then attainable. From the methods I saw employed in the last twenty years of the nineteenth century I have no doubt he was right. The reasons that made carbolic acid his earliest selection would occupy too much of your space to describe. It was chosen after a careful comparison with heat and other antiseptics in their relations to practice. Among the many qualities that led to its adoption there remain many that have not been surpassed in value by the antiseptics of to-day.—I am, etc.,

London, W.1, May 22nd.

G. LENTHAL CHEATLE.

The Medical Charities

SIR.—With Dr. Arnold Gregory's plea for the charities all those who have worked for them will heartily sympathize. His diagnosis of the situation, set forth in his three numbered paragraphs, is only too correct. That the incomes of the charities are incommensurate with the calls made upon them is not the fault of the British Medical Association, whose Council and whose *Journal* have long and often dinned this into the ears of Branches, Divisions, and members. In my view the charities need an assured subscription income at least double that which is now collected for them by their own local secretaries and through the B.M.A. Bridge drives, concerts, dances, etc., as proposed by Dr. Gregory, may with luck bring in enough in any one year to justify the effort expended on them, but they are palliatives merely, and they tend to be supported mainly by those who already do their duty by subscribing, not by the others; further, they can seldom be repeated annually with continued success. These methods are suitable for charities which appeal to large sections of the public, not for such limited communities as the members of our profession in a given area.

Dr. Gregory's idea of an endowment fund is sound enough, though £25,000 is of little use (the income would be under £900 a year); £250,000 would not be too much. This sum cannot be expected from any feasible "campaign," however "intensive"; but it can be obtained by the investment of all legacies, a policy which both the leading charities would like to put in practice, but are not able to. Last year, for instance, Epsom College spent about three-quarters of the legacies received, and

was able to invest only the remainder; this year, I understand, the prospects are much better, owing to good fortune with bequests, and I fancy the same is true for the Royal Medical Benevolent Fund. If these charities had sufficient subscription incomes all legacies could be funded, as of course they ought to be. Few practitioners who are in a position to leave charitable bequests think of the Benevolent Fund and Epsom College. If they did, the accumulation of ample endowment funds would not take very many years. You, Sir, and the Editor of the *Lancet*, have both done your share in trying to make medical testators realize this.

Dr. Gregory's suggestion for enlisting the wives of doctors appears to ignore the work of the R.M.B.F. Guild, which is run entirely by these ladies, and very well run too. I agree with him that personal canvassing is far more valuable than letter writing—but it takes up a lot of time. I trust that he will not think I am being unhelpful in deprecating his feverish week of bridge tournaments and sales of work; I wish him all success in his efforts to rouse the profession, but I feel sure that the two things to concentrate upon are annual subscriptions and legacies.—I am, etc.,

London, S.W.7, May 26th.

HENRY ROBINSON.

The Cancer Problem

SIR,—It is curious to read letters from people of such eminence as Mr. Hastings Gifford, whom I regard as among the most learned in Britain on the subject of cancer, and Mr. Lockhart-Mummery, one of the foremost of our clinicians, which take diametrically opposite views as to whether civilization has caused an increase in the incidence of cancer. In spite of the admirable reasoning from Mr. Gifford, the case can never be proved until the uncivilized are sophisticated enough to have a registrar-general's report on the causes of death, which in itself would make them so civilized as to destroy its value. We do know, however, that wild animals, including birds and fish, suffer from cancer, though most diseased animals are soon killed by their natural enemies. The evidence of missionary doctors is that cancer is common among natives; indeed, cancer of the buccal cavity, owing to betel chewing, is a commoner form of cancer in India than elsewhere in the world, though statistics as regards the total population may not be available. I have seen cancer in South African natives and the Zulus, who are chiefly vegetarians, and also among the Samoyedes in the Arctic Circle, a meat-eating race, who never see a green leaf.

Civilization has progressed to such a degree that we should expect that if cancer had existed in the remote past—as we must suppose it did, for we regard it as disordered life, and therefore it probably is as old as life itself—it ought to be more prevalent at the present time, for we must presume that the Bronze Age spoke of itself as civilized as compared with the Stone Age, the Iron Age with that of the Bronze, and so on with each succeeding advance up to the present time. There is, however, one method by which civilization influences the cancer rate which I have never seen referred to. If there are, let us suppose, one hundred causes of death, and civilization eliminates twenty of these, the same number of people will die, because they cannot live indefinitely, but now their deaths must be divided among the eighty remaining causes. This will enable the unscientific statistician, among whom most of us must be classed, to look with astonishment at the increase in the ratio of certain diseases. We have decreased the death rate from small-pox, typhoid, diphtheria, tubercle, and all surgical diseases to such an extent that increase in those

that remain must be marked, cancer among them. Whether Mr. Hastings Gifford will seize on this to support his argument or not I don't know.—I am, etc.,

London, W.1, May 23rd.

DUNCAN C. L. FITZWILLIAMS.

Toxins and Emulsions

SIR,—Since Dr. G. Norman Myers's letter in the *Journal* of March 17th (p. 504), to which we replied on March 24th (p. 557), we have been waiting for the publication of the results of his investigations, which appeared in your issue of May 26th.

The general conclusions arrived at by Dr. Myers with regard to the non-toxicity of super-lethal doses of toxin when mixed with emulsion upon subcutaneous injection confirm our findings in great detail. We commented in our letter of March 24th upon a number of points in connexion with Dr. Myers's experiments. In his paper he appears to have altered the description of his technique from "the oils and fats when mixed with aqueous solutions of lethal doses of toxins so as to form emulsions," to "aqueous solutions of the toxins were mixed with the emulsions (already formed) immediately prior to injection." This alteration is of considerable importance for, after all, these points of technique are of the essence of the problem.

Dr. Myers concludes from his experiments on injecting the layers after centrifugalization that "the toxin has a greater solubility or affinity for water than for oil," yet it is clear from his own experiments that the question of solubility in oil does not arise, and this because such solubility could not be in any way influenced by the degree of emulsification. The only change which such a fine degree of emulsification could bring about would be an increase in the rate of solution, but no alteration in the partition coefficient. Thus we can safely eliminate the solubility explanation when, from the discussion at the phenomenon necessary to explain these results. It is indeed strange that Dr. Myers should return to this solubility explanation, when, from the discussion at the end of his paper, he himself would appear to have adopted our suggestion that the phenomenon is one of adsorption.

Finally, Dr. Myers, in his original letter, wrote that he began his investigations three years ago; in his paper he has antedated it by two years; we would be interested to know if we may regard this date as now fixed.—We are, etc.,

Physiology Department, St. Mary's
Hospital Medical School,
May 23th.

A. C. FRAZER.

Strangulated Hernia

SIR,—I confess to a feeling of disappointment with Mr. Wood Power. After writing what was in many respects an excellent paper, seriously marred only by the unaccountable priority which he gave to taxis over the far more scientific postural treatment in the hope of reducing an apparently early case of strangulated hernia, he now definitely states that he sees no objection to the general practitioner employing taxis in early cases. He gives the chief causes of difficulty in reduction quite correctly as "increasing oedema and distension of the bowel due to venous stasis; and secondly, the contraction of the abdominal muscles." Quite so. Provided the constriction is not too tight, postural treatment is the scientific method of relieving venous obstruction. The spasm of the abdominal muscles in the early cases is due to pain, and morphine and locally applied warmth are the correct means of relieving this, when the spasm will relax. On

the other hand, pressure, even not unduly strong, over any part of the strangulation will increase the pain, and inevitably increase the muscle spasm. So it was in the bad old days (not so very long ago) that world-celebrated surgeons advised that taxis, if done at all, should always be done under a general anaesthetic.¹ I suppose Mr. Power would not advocate this.

But quite apart from these considerations there are so many other possible things that might conceivably mislead a man not very well versed in surgery into errors—they are all somewhat uncommon, but are fully described in many old textbooks. I am not going to discuss them here.

Mr. Power himself, in his original paper, says: "The general practitioner, as a rule, has a limited experience in dealing with such cases; it is far safer to leave the attempt to the surgeon, who is generally better fitted to judge whether taxis is advisable or not." And after this he goes on to make his unaccountable lapse, which he emphasizes and makes more definite in his letter in your issue of May 26th. Now his avowed and admirable intention in writing the original paper was to suggest methods by which "strangulated hernia should become a tragedy of the past." These are his own words. If this object was attained nothing else obviously need be said. But further on he proceeds to describe means by which Vick's mortality rate of 18 per cent. in 11,000 yearly cases might be reduced. He then gives his own mortality of 17.94 per cent. in seventy-eight cases. So Mr. Power has managed to reduce the mortality by 0.06 per cent.! We may take it for granted that Mr. Power is a skilful surgeon, and, moreover, his use of local analgesia is wholly admirable. Therefore the cause must be delay, possibly associated with injudicious outside attempts at taxis.

In many cases the patient with a hernia is quite used to it "coming down," and feels quite unconcerned about periodically replacing it himself. This fact alone should provoke thought. Then the day comes when he cannot "get it back." He has a really good "go" at it. Bad pain comes on, perhaps with vomiting. The other members of the family have a good "go" at it, and, finally, the poor general practitioner has a "go" at it, possibly without the adjective "good" in front of it. Then the surgeon sees the case—God knows how long after the onset! Consequently the mortality rate continues to be an apparent reproach to modern surgery. The rest of Mr. Power's letter does not call for comment.—I am, etc.,

London, May 27th.

ROY HUCKELL.

SIR,—On the question of taxis Mr. R. Wood Power (May 5th, p. 787) invites the opinion of the general practitioner.

I have had a long experience of country practice, in which strangulated hernia is not infrequent. I always attempted taxis, and have succeeded in all cases where seen early, with six exceptions. These six patients were placed on the inclined plane, given a dose of opium, and heat was applied to the part. After a sleep of a few hours the patient, on waking up, found the hernia in each case gone. I do not understand the objection to trying taxis in strangulated femoral hernia. In all the cases I have seen I have found it successful.

Looking back on over forty years of practice I can only recall one of my cases in which it was thought necessary to operate, and this was first seen by me on the second day.—I am, etc.,

Concealed Incision of Interval Appendicectomy

SIR,—Mr. Ernest Cowell will find the incision he writes about (May 26th, p. 947) described in the second edition of Comyns Berkeley's and my *Textbook of Gynaecological Surgery*. It is known as the Küstner-Rapin incision, and was first described in 1896. I have employed it for a great number of years in certain cases, and have very frequently removed the appendix through it. The proceeding is, as a rule, very easy, but there are occasions when it is not—namely, when the appendix is retrocolic, lying high and adherent along its whole length to the colon. The skin incision should be slightly curved with the concavity upwards, not downwards, so as to correspond with the natural creases of the part. It is not necessary to incise under the rectus muscle—a central incision will do as well.

A most important step from the point of view of future concealment is to suture the subcutaneous fat; for if this is not done the skin adheres to the aponeurosis, and when the patient stands up an ugly gutter appears, which the indrawn hair renders very conspicuous. It is also essential to keep the wound strongly compressed by a pad for several days, for otherwise a very troublesome haematoma may form in the dead space under the skin.—I am, etc.,

London, W.1, May 28th.

VICTOR BONNEY.

Criticism of Ante-Natal Work

SIR,—Although in retirement I still take an interest in the *Journal*, and especially in articles on obstetrics, and so I read Mr. A. J. Wrigley's "Criticism of Ante-natal Work" (*Journal*, May 19th; p. 891) with more care than usual. I have often thought of offering some criticism of the many articles and addresses on obstetrical subjects which have appeared during the last ten or twelve years, but I did not like to pit my limited experience as a general practitioner against that of the various male and female professors, lecturers, and specialists who were giving their experience for our benefit. And now comes Mr. Wrigley's lecture, with its exposure of some of the ante-natal work. For some years I examined all the women who engaged me, but always used the knowledge gained as a guide for the labour, and as I had not the technical skill I never attempted to correct any malpositions or think of induction. Now it seems that, quite unconsciously, I was following the correct practice.

Mr. Wrigley says: "Good work is being done by ante-natal supervision in the detection and treatment of various conditions that have been complicated by the pregnancy—for example, chronic heart disease." Some years ago, while I was talking to Dr. Archibald Donald of Manchester on ante-natal work, he said that if a pregnant woman has heart disease she'll not need to go to an ante-natal clinic to have it found out; and I agree with him. It is probable that murmurs are detected and treated, and possibly with the same results as the "malpositions" and "disproportions."

From January, 1883, to June, 1885, I was assistant to Dr. Farquharson in Coatbridge. There were over 200 confinements in the practice every year. Dr. Farquharson was a fine obstetrician who never hurried a confinement. During these two and a half years there was one woman who was ill, and she recovered. Dr. Farquharson said he had had only two or three cases of puerperal fever in his twenty-one years' practice in Coatbridge, and no deaths. (He attributed the recoveries to the administration of chlorate of potash, as recommended by the great Simpson.) Eclampsia was unknown. I remember that all the patients had an abundant vaginal secretion, which stuck to the fingers. The children were fat and healthy, and one patient after another would say, "Aye, it was

fed on tatties and soor milk." These women lived largely on porridge and milk, with tea and bread-and-butter for breakfast; potatoes and sour milk, or Scotch broth, or potatoes and herring, for dinner; tea, bread-and-butter at tea-time; and perhaps more porridge, or peas brose, and buttermilk for supper. Beef and mutton were at a minimum. That is, their diet was laxative and diuretic, and did not irritate either the heart or the kidneys, and the kidneys could easily excrete any poisons generated in the foetus or the mother. Is the secret for the prevention of eclampsia and some of the puerperal fever not to be found in a plain, non-irritating diet? Buttermilk (sour milk) can be obtained in only a few districts, but ordinary milk could be skimmed and made into koumiss.

It would be difficult to get women to feed on the Coatbridge diet, and, alas, for the Scotch broth, vegetables are very dear, and herrings are now dear and scarce; formerly vegetables and herring were abundant and cheap. On the other hand, we still have eclampsia and puerperal sepsis in our midst, and the labours are dry, with hardly any vaginal secretion to protect the mucous membrane. It would be interesting to know how midwifery practice is in Coatbridge to-day. If this letter should meet the eye of any doctor practising in the Gartsherrie Rows (the Lang Raw, Cornish Raw, Wee Square), Ellis's Buildings, perhaps he will record his experience for our benefit.—I am, etc.,

Dunblane, Perthshire, May 24th.

JAMES GARDNER.

Capacity for Work after Fracture of Spine

SIR,—Dr. Owen L. Rhys, in his most interesting paper, published on April 14th (which, owing to mischance, I have only just seen), states that twelve out of 270 patients with fractured spine were able to return to their ordinary work. He does not differentiate here between cases where the bodies were crushed and cases where only transverse processes were fractured. Would he very kindly state exactly how many men in his series with crushed vertebral bodies were able to return to their full work, as I am collecting statistics on this point. My own experience is that very few of such cases are ever able to do their full work again.—I am, etc.,

PAUL BERNARD ROTH, F.R.C.S.

Newcastle, Staffs, May 26th.

Medical Referees

SIR,—Dr. R. M. B. MacKenna (May 26th, p. 965) calls attention to a question of the first importance—the semi-divine powers delegated to medical referees. It seems that the written opinion of a referee, based upon whatever evidence, is held sacred (officially) for all time: that it may not be questioned, no matter how mistaken and prejudicial it may be. It is no exaggeration to assert that if a medical referee, having gone mad or colour-blind, or merely pig-headed, decrees that a white man is black, that white man is black (officially), and must continue to be regarded as black. I put this to a medical referee the other day. He agreed whole-heartedly.

If there be any who question the assertion I shall be happy to supply evidence based upon cases that have come within my personal knowledge.—I am, etc.,

Walsall, May 28th.

FRANK G. LAYTON.

Nutrition

SIR,—Dr. Campbell Watt, in his letter of February 17th, after sincerely congratulating "the English working classes on the variety and quality and quantity of their diet," and upon the fact that they do themselves uncommonly well, modified this slightly in his letter of April 28th by stating that statistics show that "most, except the lowest-paid classes, consume more than their requirements." He thus gives the impression that it is only a small minority of the English who suffer from malnutrition.

Dr. Campbell Watt advocated, on February 17th, a practical study of the problem, examining individuals in their everyday life. This is done every year by medical officers of health and various Commissions, who have the necessary experience not to confuse the effects produced by malnutrition with the effects due to "ill-health, heredity, congenital defect, or to physiological or psychological reactions to environment other than food."

The M.O.H. for Bethnal Green in his report for 1932 states: "A large proportion of the population are living at an extremely low level." The M.O.H. for Birmingham—1932: "Owing to the long-continued and widespread unemployment in the district many of the children were not thriving, through lack of proper nourishment." The M.O.H. for Wolverhampton—1932: "There is a distinct increase in malnutrition figures of school children. It is doubtful whether the figures represent the whole picture. There appears to be established here a definite link between unemployment and the malnutrition of children." The Social Survey Committee of the Hull Community Council published a report in the middle of 1933, stating: "The diet of unemployed men's children showed a serious omission of nutrition foods, and cannot but result in continuous ill-health." A special committee of the Save the Children Fund came to the following conclusions: "There are many thousands of children within the danger zone of impairment of physique and health, and there was a residuum whose health is already impaired and whose future as citizens and as parents is being impeded by the conditions under which they are now compelled to live." Dr. E. H. T. Nash, at the B.M.A.'s 101st Annual Meeting, said: "There was a serious increase in mortality among young adults of slum population, as a result of poor nutrition due to poverty."

These reports, if space permitted, could be multiplied tenfold, but I think that they should convince Dr. Campbell Watt that the English as a whole do not do themselves so well. He may, however, assert that it is not due to underfeeding, but simply to a faulty balance in the rations consumed. In practical life one must realize that the amount and quality of rations consumed is largely an economic question, and depends upon the income of the family. We have already seen in these reports that it is this factor, and not a faulty balance, that causes malnutrition. Let us, however, take a few English families' budgets as instances:

In the Finsbury (London) M.O.H. report, 1932, several are listed, of which these are representative: Ten persons living in two rooms, 14s. 6d. wages, 17s. 6d. relief; eight persons in one room, wages £1, relief 18s.; nine persons in two rooms, transitional benefit £1 17s. 6d.; nine persons in two rooms, wages £1 10s. Hammersmith (London) M.O.H. report, 1932: Husband, wife (expectant mother), three children, 10, 8, and 5, net income after deduction of rent 19s. 3d. The dietary of this family is listed in full. The meat (5 lb. of target mutton) is bought in the market on Saturday night for 1s. Stale bread only is used, etc.

After deducting such items as "rent, coal, clothing, beer, tobacco, artificial silk stockings, dances, cinemas, and football matches" from these typical family budgets I am sure that Dr. Campbell Watt will easily compile a dietary which is sufficient in quantity and quality.

As for the B.M.A. diets, Dr. McGonigle, honorary secretary of the B.M.A. Nutrition Committee, in a letter

to the *British Medical Journal* of July 29th, 1933, stated that "there exists to-day no generally accepted, standardized, or satisfactory method of assessing the nutritional state of individuals"; also "there exists considerable doubt as to the possibility of assessing with any degree of accuracy the true nutritional condition of any given individual" by the means of a formula combining in various ways height, weight, and age. So that any dietary at our present stage of knowledge, purporting to maintain a hypothetical normal nutritional state, must of necessity be unscientific and unreliable. Apart from the fact that, owing to economic conditions, many English families are not even receiving the B.M.A. standard dietary, it appears as if it would be rather difficult for any adult male to maintain normal health on 10d. a day for meals, an average of about 3½d. per meal, even if he had a balanced diet.

Dr. H. A. Jardine, in her letter of February 24th, shows clearly how abundant food stores, ironically termed "surplus," are being destroyed. In addition, import duties and restriction quotas raise the prices and tend to place the food still further out of the grasp of our undernourished countrymen. Famine does not exist; a large proportion of food stores is either lying idle or is being destroyed; a large proportion of the population is suffering from the effects of malnutrition. The remedy to humanitarian scientists is obvious. The compilation of dietaries that to some extent justifies these conditions does not conform to the purpose of our profession.—I am, etc.,

London, E.5, May 23rd.

S. LEFF, M.B., B.S.

The Control of Obesity

SIR,—For those who may also be struggling against the temptation of the flesh in the shape of fat, starch, pastry, bacon, and potatoes, may I be permitted to give another personal experience of Dr. Douthwaite's No. 1 diet, to cheer up those who may be depressed by the experience of "M.D." (May 19th, p. 919).

Beginning on April 22nd, and adhering to the diet, but with almost complete substitution of bread or toast by "energen" or "ryvita," my results are as follows:

April 22nd,	weight	12 st. 8 lb. (in pyjamas)
		(normal for height, 10 st. 8 lb.)
" 29th,	"	12 st. 5 lb.
May 6th,	"	12 st.
" 13th,	"	12 st.
" 20th,	"	11 st. 11 lb.
" 27th,	"	11st. 10 lb. (result of a little butter and scones).

While the self-denial of butter and potatoes, in particular, cannot be described as "pleasant," and though one rises from the table still hungry—as all good physicians say one should—I cannot honestly say there has been any real distress beyond an annoyance at seeing others at table gorging themselves on cheese, boiled puddings, and pastry. The sleeplessness is common to both "M.D.'s" and my experience, and was notable in my case, as I am a very sound sleeper, but it passed off in the third week entirely. Physical fatigue was perhaps undue in the third week, but mental concentration was never impaired, and during this fourth week was particularly tested.

I agree with "M.D." that fat and sugar are probably the prime causes of obesity, and it is just the butter and bacon that one misses. I fancy the physical fatigue may be due to the limiting of carbohydrate. But personally I intend to "stick it" to below 11 st., and my main reason is because I have no trace of a heretofore constant flatulent indigestion, and because of the entire disappearance of "rheumatic" pains and of a beautiful lessening of "embonpoint."

I cannot agree that to diet is to be miserable, and, whilst to be fat may cause one to laugh, it is also apt to

be a cause of laughter in others. One great point of this diet is that it does not interfere with one's working. Personally I have considerable intellectual work and forty or fifty miles motor driving daily, and at no stage have I felt unfit for it.—I am, etc.,

May 22nd.

"SLIMMER."

Alleged Poisoning by Oysters

SIR,—The case of Mr. Charles Frederick Wimble against the Royal Victoria Hotel, St. Leonards, for supplying him with oysters which were held by the jury to have brought about an attack of typhoid fever is of very great importance, as it raises the question whether our existing laws as applied to such cases merit revision.

Here we have a case of a man who goes to a hotel where he partakes of a meal which, among other things, consists of a dozen or so of oysters. Some time later he is found to be suffering from typhoid, and he thereupon concludes that the oysters which he had eaten were solely responsible. He sues the hotel proprietors for damages, and a sympathetic special jury find that the oysters were the actual and only cause of the attack of typhoid and award £525 in damages. Apparently from the report published there was no evidence whatever that either the oysters in question, or any other oysters sold in that neighbourhood, had been contaminated with typhoid bacilli, and apparently also no attempt was made to find out if there was a typhoid carrier handling Mr. Wimble's food in his own home or elsewhere. In October there are still numbers of flies which are quite capable of carrying *B. typhosus* from any exposed excreta on to Mr. Wimble's milk-jug, cheese, cold meat, etc., and I now suggest that it is infinitely more probable that the disease in question was communicated in this way. It has been clearly demonstrated some time ago that oysters which were artificially contaminated with pure cultures of *B. typhosus* when placed in fresh sea-water were able to free themselves from the germs completely in twelve hours. In other words, the common oyster has a wonderful power of rapidly freeing itself from infective germs by means of an excellent mechanism of its own. I consequently think that it is highly undesirable that a decision such as this should be allowed to go by unchallenged.

Should the question be permitted to pass without being fully and properly sifted, discredit will be placed on the character of a very excellent and desirable article of human food, and an important industry, which has been seriously neglected in the past and for which strong efforts are now being made to help it to revive, will have its future seriously prejudiced.

I now beg to give it as my opinion that cases such as this, where questions of a highly technical nature are at issue, should not be submitted to the decisions of juries of laymen, but, on the contrary, should only be put before juries of men who have had thorough scientific training.—I am, etc.,

Kirk Michael, May 26th.

E. G. FENTON.

SIR,—The success plaintiffs have had in recent years in actions for negligence should not pass unnoticed. To the cases of fur dermatitis must be added the many instances of food-poisoning and the present example of typhoid. If the inference drawn from daily observations be correct, the incidence of gastric influenza, to which food-poisoning, paratyphoid, typhoid, typhus, and dysentery belong, is steadily rising, and much injustice will be caused by upholding the present procedure. As evidence points to our having entered, in 1930, into a long era of gastric influenza, both law and medicine would do well to pay immediate attention to the susceptibility of the individual and to re-sift the present-day knowledge of epidemics. That a new inquiry is urgently needed is

shown by the omission in this case of any reference to the fact that the epidemic of typhoid in Hastings coincided exactly with the epidemics in Yorkshire, the Midland counties, and the Balkans. In Yorkshire the epidemic began in a town where the water supply was above reproach. It spread to another town where the water supply contained typhoid bacilli years before the epidemic began, and still does after the epidemic has vanished. These facts, to which must be added the most important one of all, that epidemics are cyclical, disprove the view that infections begin through outside contamination. Even carriers do not play the part accredited to them. Indeed, the evidence points to most epidemics arising within the individual at the instance of climate.

For an infection to become full-blown it is necessary for the bacteria responsible to have undergone a series of mutations, and herein lies the explanation of susceptibility. Climate causes certain mutations to occur, and the steps are more quickly trodden in diseased than healthy subjects. Taking any collection of individuals an outside factor having no connexion whatever with any bacterial body may so lower the resistance of one or more as to enable the final mutation to occur. In others it may advance the mutation a few steps only, and in a third class, where there are no pathogenic micro-organisms, may have no influence. This explains why in an epidemic the manifestations of disease vary and different micro-organisms are found.

The Hastings epidemic was no different from any other, and as cases of typhoid occurred where no oysters were taken and others who partook of the supposedly contaminated fish failed to get typhoid, the only just inference to draw is that any factor might have precipitated the infection in the plaintiff. Even a pure article of food at a certain time may precipitate the common cold and the respiratory form of influenza, but it would not be fair to allow an action to be brought against the purveyor.

Epidemics of so-called food-poisoning were particularly rife during the last quarter of 1933, and such large sums of money have been paid to complainants to avoid the publicity of a court of law as to make one fearful of speculative legal actions. Of course, no effort should be spared to render food as natural and pure as possible, but if any success is to be achieved in reducing the incidence of these infections it is to be obtained only by making the individual healthier.—I am, etc.,

London, W.1, May 23rd. J. E. R. McDONAGH, F.R.C.S.

Poisoning by Ground Ivy

SIR,—I have read with interest the letter by Dr. W. G. Aitchison Robertson in your issue of May 12th (p. 872), and also that by Dr. F. William Cock (May 19th, p. 922).

In the first place, may I raise the question as to why Dr. Robertson fails to use scientific botanical nomenclature in his letter, for in "one fell swoop" he appears to confound three natural orders of plants by his use of the term "ground ivy" and the subsequently appended remarks. May I be permitted to refer to these three orders?

1. Ground ivy, as such, is the recognized popular term for a plant of the order Labiataceae, a small purple-mauve flower of bitter aromatic smell, and used by the ancients to flavour beer—verily a neglected, common, not unagreeable, harmless hedgerow plant.

2. Dr. Robertson may have been referring to some member of the *Hedera* genus, possibly a variant on our *Hedera helix* or common ivy. This plant is a member of the Auraliaceae. It is bitter in flavour, but carries abundant yellow-green flowers, eagerly sought by late-flying moths, etc. Later it bears crops of nutritious black berries, which are consumed with avidity by various wild birds. This plant is certainly devoid of ill effects on the

large majority of people; but it is quite conceivable, as Dr. Cock states, that certain people may possess an idiosyncrasy to it.

3. Then there is the well-known "poison ivy or oak," *Rhus toxicodendron*, an American immigrant to this country, and one which is justly infamous as a contact poison plant.

I can bear out Dr. Cock's statement that the "tea" from the leaves of *Hedera helix* has a country reputation as an anodyne in carcinoma. In conclusion, may I plead for the more common use of scientific terminology in describing botanical subjects in connexion with medical science, for unfortunately—as can be seen from this correspondence—Dr. Robertson's letter, while being interesting, leaves considerable doubt in the mind as to what plant really causes the symptoms he describes.—I am, etc.,

London, S.W.1, May 22nd.

DAVID H. HALER.

SIR,—I thought that I had made it plain that it was that very common variety of ivy which grows over banks and under trees in almost every garden, and which was known to the older botanists as "ground ivy" or *Hedera terrestris* (Sowerby). It is still almost universally known in country districts by this name, and has not the slightest relation to the labiate, *Nepeta glechoma*, either in appearance, scent, or habitat. The latter grows on hedgerows or in open pastures, impoverishing the ground, and so could not in the remotest degree be confounded with the creeping ivy to which I refer.

My object was merely to draw attention to the danger of handling this very common plant, and to help in the recognition of a painful condition, the cause of which might be easily overlooked. My impression is that the idiosyncrasy to this plant is not so infrequent as might be imagined. One correspondent informs me that he obtained some relief from frequent applications of calamine lotion and sedative doses of potassium bromide and valerian. The dermatitis which this variety of ivy gives rise to is very similar to that produced by toxicodendrol, lobinol, or paraphenylenediamine.—I am, etc.,

Bournemouth, May 29th. W. G. AITCHISON ROBERTSON.

Industrial Cancer and Blood Pressure

SIR,—Your excellently concise summary of present knowledge regarding cancer and chemical stimuli prompts me to point out that, as the result of some research work I have done in connexion with workers who are liable to pitch cancer, I find predisposition is closely associated with a modification of the basic (diastolic) blood pressure. When this is increased there is an increased pressure on the blood in the arteries, with the result that the movements of the blood cells are modified, and the red cells are unable to carry their full complement of oxygen to the tissues, which are consequently lowered in vitality.

A prolonged exposure over some years to small quantities of carbon monoxide gas tends to reduce the oxygen-carrying capacity of the blood, whilst raising its basic blood pressure. It follows that a man who starts work in a pitch or fuel works with his blood below par is already predisposed, and similarly a man of 60 who hitherto has escaped pitch warts becomes more and more liable to them as senile anaemia sets in. In both of these types the basic blood pressure is raised and an adequate supply of blood fails to reach the tissues.

Workers in fuel works may be classified as: (a) good health, houses, and homes; (b) indifferent health, houses, and homes; (c) poor health, houses, and homes. It will be found that the age at which these three grades develop pitch warts is somewhat as follows: (a) 50 to 60; (b) 35 to 50; (c) 20 to 35. A hereditary tendency is always closely associated with the blood group and with its oxygen-carrying

capacity, whilst a family tendency to right or wrong feeding simply accentuates the association.

When the oxygen supplied to the tissues is reduced in quantity the cells divide rapidly in order to increase the area of absorbing surface. This is shown in hyperpiesia in the form of arteriosclerosis, when the raised basic pressure, by compressing the openings of the vasa vasorum, prevents an adequate supply of oxygen being carried to the tissue cells of the arterial walls. It is also well to note that a large percentage of these patients die from cancer. In parasitic tissues the parasite demands oxygen, which it derives from the tissue cells; these cells consequently are deprived of oxygen, and divide rapidly in the hope of obtaining more, the superfluous division forming a "growth." In patients whose blood is affected by animal parasites, as in syphilis, as well as in those whose blood is stated to be affected by a "virus," one finds that the basic blood pressure is always raised, and consequently the carriage of oxygen to the tissues is reduced.

In patients suffering from industrial cancer there are two constant factors present—namely, a prolonged exposure to CO gas and a raised basic pressure, both of which tend to reduce the supply of oxygen to the tissues. The introduction of poisons or toxins into the system tends to raise the pressure.—I am, etc.,

Swansea, May 27th.

G. ARBOUR STEPHENS.

A Case of Abortus Infection

SIR,—An unmarried woman, aged 39, developed a rise of temperature in March last, diagnosed provisionally as due to influenza. The temperature subsided within fourteen days. In the fourth week a pronounced rise led to further investigation, the Clinical Research Association reporting that the blood agglutinated *Brucella abortus* in 1 in 1,000 dilution. The interesting feature about this case is that apart from a mild headache the only physical sign was a very severe inflammation of both nipples, lasting a few days in the week of relapse (fourth week). Prior to this the nipples were very undeveloped. No further relapse has occurred at the end of nine weeks.—I am, etc.,

Crewe, May 15th.

W. L. ENGLISH.

Reflex Inhibition

SIR,—The existence of an element of reflex action in epilepsy is well known (examples are given by Kinnier Wilson). For example, a flick on the nose of one patient would produce a fit. No less instructive are cases where a particular stimulus or act will prevent an attack. The following case illustrates this.

A male patient, 21 years of age, has suffered from occasional fits since childhood. He can always tell when a fit is coming by a tingling sensation in his left leg. He then calls out to whoever is in the house for help. This help, as described by his mother, consists in immobilizing his left leg, by kneeling on his toe (while he is sitting down), and pressing downwards on the knee. If she "gets to him in time" the fit can always be prevented in this way.

A possible explanation of this phenomenon is that the general abnormal cortical excitation, which apparently occurs in a fit, in such cases can commence only from a particular area of the cortex. We may suppose that for the cortical excitation to commence and spread, the chain of events—aura, localized muscular movement (of the leg in this case), unconsciousness, and general muscular movement (convulsions)—must proceed uninterruptedly, if at all. If this chain of events be interrupted by preventing the onset of localized muscular movement (of the leg here), general abnormal excitation of the cortical area concerned is prevented (or perhaps its abnormal spread is prevented). An analogy would be the prevention of general cortical

inhibition (of sleep—Pavlov) by some external stimulus or act (for example, preventing a person sleeping by shaking his shoulder).—I am, etc.,

Perivale, Middlesex, May 15th.

R. L. WORRALL.

Extra-Licentiatees of the College of Physicians

SIR,—In his interesting review of Dr. Hobhouse's edition of Claver Morris's diary Sir D'Arcy Power repeated in your last issue a not uncommon misconception of the nature of the extra-licence of the Royal College of Physicians of London.

The extra-licentiatees could practise anywhere in England save within London and the circuit of seven miles. This licence was first granted in 1660 under the new Charter of Charles II, after examination by the President and the elects—not, as in the case of the licence to practise *intra urbem*, by the Censors Board. In 1859, after the passage of the Medical Registration Act of 1858, the College of Physicians made a new by-law enabling their extra-licentiatees, on payment of five guineas, to become licentiatees, with the right to practise in London.

Claver Morris became an extra-licentiate in 1683 because he wished to practise in the provinces as a physician. The degree of D.M. would entitle him to do this, but could not be granted at Oxford until eleven years had elapsed from his baccalaureate—that is, in 1691.—I am, etc.,

London, W.1, May 28th.

CECIL WALL.

Chemical Factors in Germinal Impairment

SIR,—It is amusing that Dr. W. Spencer Badger did not, in his letter (May 26th, p. 965), advocate that the State should forbid the distribution of literature which recommends chemical contraceptives but merely the "sale" of such literature. However, proof has not yet arrived that a chemical contraceptive can cause the birth of a defective individual. And if it comes to be proved that the use of chemical contraceptives can cause the production of a serious number of defectives, the better policy should be followed of taking a restrictive law off the statutes instead of putting another one on. Practically all the birth control and eugenic problems would be entirely, or very largely, solved by my formula: Sterilization and abortion should be available to any person with two children, and no woman of the poorest classes should have more than two confinements.—I am, etc.,

London, S.W.7, May 26th.

B. DUNLOP.

Osteopathy

SIR,—Mr. A. S. Blundell Bankart, referring to the Osteopaths Registration Bill (in his letter to the *Journal* of May 19th), says he thinks "that medical men at least should be acquainted with the truth about this movement." His attempts to make plain the truth about osteopathy are sadly misleading to those who know little about the subject, and are rather amazing to those of us who are familiar with osteopathic work. To say that "osteopathy has nothing whatever to do with 'bone-setting' or with manipulative surgery or the therapeutic manipulation of stiff joints," is a statement which Mr. Bankart would find very hard to substantiate, and to follow that statement immediately with the information that "manipulative surgery is now a recognized branch of orthodox practice" would suggest to his unbiased readers that, as surgeons are now beginning to use manipulation as part of orthodox surgical practice, there is no room for the osteopath in this line of work.

Mr. Bankart would have us believe that osteopathic work is concerned with displacements of the spinal

vertebrae and that these displacements cause direct pressure on the blood vessels and nerves leaving the intervertebral foramina. I believe this to be an entirely erroneous interpretation of present-day osteopathic principles. Certainly the osteopath is concerned with even the least disturbance of blood and nerve supply to any part of the body, and he is trained to recognize abnormalities in the spinal column or elsewhere which give rise directly or indirectly to interference with the circulation and nerve stimuli. As I understand it, these spinal displacements, which Mr. Bankart describes as imaginary, are, in the main, static fixations of articulations which have been carried beyond the normal range of movement, and held in abnormal positions by sustained unequal tension of ligaments, muscles, and surrounding soft tissues. If the abnormal condition of the joint and surrounding tissue is allowed to continue it eventually gives rise to either a local anaemia or congestion. This in turn results inevitably in disturbance of function in that part of the body, "remote" or otherwise, which is dependent on the blood and nerve supply from the affected area. Owing to the highly cultivated tactile sense, which can only be developed by years of special training, the osteopath is able to detect these fine deviations from the normal, vertebral or otherwise, which are usually not apparent to the surgeon.

Mr. Bankart classes osteopaths with chiropractors, and dismisses them both as an American "stunt." As I know nothing about chiropractic work "I must not express an opinion, but I am sure that many medical practitioners who make use of osteopathy will agree with me that the work is based on simple and sound pathological teaching, and the results achieved by a good osteopath may be safely left to speak for themselves. I am, etc.,

DOROTHY WOOD, M.R.C.S., L.R.C.P.

London, W.1, May 23rd.

The Services

COMMISSIONS IN THE R.A.M.C.

The War Office announces that applications are invited from medical men for appointment to commissions in the Royal Army Medical Corps under the new conditions announced recently.

Candidates will be selected for commissions without competitive examination, and will be required to present themselves in London for interview and physical examination on or about June 6th, 1934. They must be registered under the Medical Acts, and normally must not be over the age of 28 years.

Successful candidates will in the first instance be given short-service commissions for five years, at the end of which period they may either retire with a gratuity of £1,000 or apply for a permanent commission. Permanent commissions will be given to officers selected from among those who wish to make the Army their permanent career.

Full particulars of the conditions of service and emoluments, also forms of application, may be obtained on application, either by letter or in person, to the Assistant Director-General, Army Medical Services, the War Office, London, S.W.1.

THE I.M.S. DINNER

The annual dinner of the Indian Medical Service will be held at the Trocadero Restaurant, London, on Wednesday, June 20th, at 7.15 p.m. Major-General Sir Leonard Rogers, K.C.S.I., C.I.E., F.R.S., will preside. Tickets and all particulars may be had from the joint honorary secretary, Sir Thomas Carey Evans, Hammersmith Hospital, Duane Road, W.12.

Universities and Colleges

UNIVERSITY OF OXFORD

In a Convocation to be held in the Sheldonian Theatre on Wednesday, June 20th, at noon, it will be proposed to confer the degree of D.Sc., *honoris causa*, upon Professor Archibald Vivian Hill, F.R.S., M.A., Sc.D. (Cambridge), nominated by the Chancellor on the occasion of the Encaenia following his installation.

The President and Fellows of Magdalen College have elected John Carew Eccles, M.A., D.Phil., Staines Medical Fellow of Exeter College and formerly Rhodes Scholar of Magdalen College, to an official Fellowship and Tutorship of the College in Natural Science. Dr. Eccles, who will take up his new duties on October 1st, 1934, is a graduate in medicine of the University of Melbourne, obtained first-class honours in the Oxford Final School of Natural Science (Physiology), and was awarded in 1927 the Christopher Welch Scholarship and in 1932 the Rolleston Memorial Prize.

UNIVERSITY OF CAMBRIDGE

Dr. G. Norman Myers (Sidney Sussex College) has been appointed university demonstrator in pharmacology for a period of three years, and Dr. H. A. Krebs of Hamburg university demonstrator in biochemistry for the same period.

Dr. Frangcon Roberts has been appointed an examiner for the Diploma in Medical Radiology and Electrology, 1934, Part II, in the room of the late Dr. Stanley Melville. Mr. G. Stead, M.A., and Professor Sidney Russ, D.Sc., have been appointed examiners for this diploma, Part I, 1935; and Dr. A. E. Barclay, Dr. G. H. Orton, and Dr. E. P. Cumberbatch examiners for Part II, 1935.

At a congregation held on May 26th the following medical degrees were conferred:

M.D.—The Hon. W. S. Maclay, M. D. Nosworthy, R. W. Windle, J. B. S. Lewis.
M.B.; B.Chir.—G. W. Whittall, E. R. Hargreaves.
M.B.—J. Glyn Jones.
B. Chir.—C. M. Barker.

Fearnside's Scholarship

The E. G. Fearnside's Scholarship, which is for clinical research on the organic diseases of the nervous system, is open to members of the University or of Girton or Newnham Colleges who are graduates or titular graduates in medicine, or to graduates or titular graduates in arts who have passed Part II of the Natural Sciences Tripos. Applications must be sent to the Registry of the University before June 27th, 1934.

UNIVERSITY OF LONDON

GUY'S HOSPITAL MEDICAL SCHOOL

The following awards have been made for 1934:

Entrance Scholarship in Arts (value £100): H. F. Lunn. War Memorial Scholarship in Science (value £200) and Entrance Scholarship in Science (value £100): Divided between A. Bloom and A. R. Bradley. Confined Scholarship in Science (value £100): Divided between D. Tumasvin and H. Wormald.

UNIVERSITY OF LIVERPOOL

The Council has appointed Henry Cohen, M.D., F.R.C.P., lecturer in medicine in the University, to the chair of medicine, as from October 1st, 1934, in succession to Professor John Hay, who retires at the end of the current academic session.

SOCIETY OF APOTHECARIES OF LONDON

The following candidates have passed in the subjects indicated:

SURGERY.—P. E. Cresswell, M. T. Curran, R. Fleming, S. Kay, S. Klein, R. Sugerman, C. E. Wetherall, W. E. White.
MEDICINE.—P. C. Alexander, C. N. Chowdary, G. W. Hardy, C. C. Joannides, S. Kay, A. G. Manley, J. Mason, S. E. Roberts, E. C. Rowlands.
FORENSIC MEDICINE.—P. C. Alexander, F. M. Chalkley, M. V. Matthew, M. A. Walsh Conway.
MIDWIFERY.—A. E. Ginn, L. A. Lewis, H. Paroulakis.

The diploma of the Society has been granted to P. C. Alexander, A. E. Ginn, G. W. Hardy, S. E. Roberts, E. C. Rowlands, R. Sugerman, and C. E. Wetherall.

Obituary

ANDREW FULLERTON, C.B., C.M.G.

M.D., M.Ch., F.R.C.S.I., F.A.C.S.

Ex-President, Royal College of Surgeons in Ireland; Emeritus Professor of Surgery, the Queen's University of Belfast; Consulting Surgeon, Royal Victoria Hospital, Belfast, and Belfast Hospital for Sick Children; Colonel A.M.S.

We announced in our last issue, with deep regret, the death on May 22nd of Professor Andrew Fullerton, which, while not unexpected, has filled the hearts of his colleagues in the Belfast Medical School with a sense of irreparable loss. He was born in 1868, the son of the Rev. Alexander Fullerton of the Methodist Church in Ireland, and received his education in Lurgan College and the Queen's College, Belfast. Already distinguished as an undergraduate, he obtained first-class honours in the M.B. examination of the Royal University of Ireland in 1890, and the M.D. degree in 1893. In 1901 he became a Fellow of the Royal College of Surgeons in Ireland, and in 1913 he proceeded to the M.Ch. degree of the Queen's University of Belfast. Some four years after obtaining his qualification he spent in the West Kent Hospital, Maidstone, and the Miller Hospital, Greenwich; returning to Belfast, he commenced practice in 1894. He was for a time engaged in general practice, but, as an honorary demonstrator of anatomy under the late Professor Symington, was acquiring the accurate and detailed knowledge which was the basis of his surgery.

His first hospital appointment was to the surgical staff of the Belfast Hospital for Sick Children, and shortly afterwards, in 1902, he was appointed an assistant surgeon to the Royal Victoria Hospital. He served these institutions with unwearied energy and skill for over thirty years, and gained for himself the affection of his colleagues and the unshaken confidence of all who knew him. In 1915 he had the honour of being invited to become a consulting surgeon to the British Expeditionary Force in France with the rank of Colonel A.M.S., and his record of service there not only confirmed the wisdom of this appointment, but brought a wider recognition of the Belfast school of surgery. He was gazetted C.M.G. in 1916, C.B. in 1919, and was three times mentioned in dispatches.

In 1922 he was elected an Honorary Fellow of the American College of Surgeons, and in 1924 he succeeded Professor Thomas Sinclair in the chair of surgery in the Queen's University of Belfast. In 1926 he became President of the Royal College of Surgeons in Ireland, being the first surgeon resident outside Dublin to hold this office. In 1931 he was president of the Association of Surgeons of Great Britain and Ireland. He was also a past-president of the Ulster Branch of the British Medical

Association, of the Ulster Medical Society, of the Belfast Medical Students' Association, and of the Queen's University Services Club. He had joined the British Medical Association in January, 1893, and was a member of the Representative Body in 1906 (Toronto), 1907 (Exeter), 1908 (Sheffield), and 1909 (Belfast). On the last of these occasions he also served as honorary secretary of the Section of Diseases of Children, becoming vice-president of that Section at the Annual Meeting at Aberdeen in 1914. When the Association met at Cardiff in 1928 he was vice-president of the Section of Surgery.

Professor Fullerton was a prolific writer on surgical subjects, and published some seventy papers in various journals. His most important contribution was the article on "Gunshot Wounds of Kidney, Ureter, and Bladder" in the *Medical History of the War*. As a urologist he established for himself an international

reputation: he made many original observations of importance, being the first to note the significance of unilateral diuresis, and to employ the retroperitoneal exposure of ureters in the early diagnosis of renal tuberculosis. In 1930 he delivered the Campbell Oration, taking as his subject "Progress in Urology." His patience and care were apparent in his case-taking, in which no relevant detail was too minute to escape record. A rapid and skilful operator, his fertile mind was continually employed in the evolution of some improvement of technique by which the surgical risk to his patient might be lessened or his comfort enhanced. He loved his teaching because he loved his subject and he loved his students. His own energy and enthusiasm seemed to have endowed him with enduring youth, and attracted to him the unstinted devotion of his pupils. He was profoundly moved when, on his resignation last October from the professorship of

surgery in the Queen's University of Belfast, he was made the recipient of a silver salver from his class.

Andrew Fullerton was a man of singular directness. His inherent simplicity and honesty rendered him incapable of guile. He had the gift of making friends, and with him friendship was lifelong. His principal recreation was golf, and it was a source of pride to him to have been elected captain of the Royal County Down Golf Club at Newcastle. He was a Past Master of the Queen's University Masonic Lodge, and was a Prince Mason.

He was twice married; his first wife, who died in 1926, was Caroline, daughter of the late Mr. Thornton Bulloch; the children of this marriage are two sons and a daughter. He is survived by Mrs. Fullerton, who is the daughter of the late Rev. R. D. French and the widow of the late Mr. Randall Cooney, F.R.C.S.I. Her unremitting care did all that was possible to mitigate the suffering of a long and painful illness, borne with magnificent courage and fortitude.

[The photograph reproduced is by Messrs. Lafayette.]

Mr. GEOFFREY JEFFERSON writes:

The death of Andrew Fullerton robs not only the Belfast school of one of its most distinguished members, but many others of a friend whose sincerity and steadfastness will keep his memory green. Private friendship is not a subject for public parade, but I must add my meed of praise for those qualities which to me did him most honour. Chief among these were his complete honesty and integrity, next his application and his industry, then his pride in his university and his city. For Belfast and its medical school, and for Queen's University as a whole, he had the greatest love. He believed in their importance implicitly, as well he might, but he knew that a university must deserve respect, not merely claim it. He knew that corporate virtue is won only by the untiring efforts of individual men, and he was primarily, all for work. He won many honours, but he thought of them chiefly in relation to his university rather than as personal gains. Eventually he learned also how to play, and certainly his captaincy of the Newcastle Golf Club, County Down, was almost, of all his later honours, that which most greatly pleased him. Like many people with definite and individual personalities he could not hope to please everybody, nor did he wish. But he knew when to make concessions, and the affection and respect of his juniors, as well as of his peers, were the return of what he gave to them. Personally I mourn the loss of a friend who is, as all true friends must be, quite irreplaceable.

DAVID OGILVY, M.D.

Medical Superintendent, L.C.C. Mental Hospital, Epsom

We had to announce, with much regret, in our last issue the death, on May 13th, of Dr. David Ogilvy, medical superintendent of the London County Mental Hospital, Long Grove, Epsom. Dr. Ogilvy was educated at Trinity College, Dublin, where he distinguished himself in surgery in his final examination, and took his M.D. degree in 1899. He was a good Rugby football player, and played for his university. He held the post of surgical resident at the Jervis Street Hospital, Dublin, and was for a time medical assistant at the Central Criminal Asylum, Dundrum.

In 1899 he began his career in psychiatry, and came under the influence at Wakefield of that distinguished physician Professor Bevan Lewis. He proceeded thence to Banstead Mental Hospital in the London County Council service, where he rose to the position of third assistant medical officer under Dr. Claye Shaw. In 1902, on the opening of Horton Mental Hospital, he was transferred as second assistant, and two years later was promoted to senior assistant medical officer. At this well-known hospital he was later brought into association with the late Dr. J. R. Lord, whose keenness and interest no doubt influenced Ogilvy's outlook.

In March, 1912, he was promoted to be medical superintendent of Long Grove Mental Hospital, in succession to Sir Hubert Bond, on the latter's appointment to be a Commissioner of the Board of Control. He realized that he had entered at this hospital on a distinguished heritage, and he faithfully devoted the remaining twenty-two years of his life to its welfare. His was perhaps a conservative mind, but it was never closed to new ideas and impressions. In this respect one may instance the interest he took in the development, on progressive lines, of occupational therapy in both male and female wards, and the fact that to his persistent advocacy was due the employment of a male occupations therapist for the prosecution of helpful occupations among male patients in fuller measure than could, in his judgement, be secured by confining the initiation of such work to women officers, as

was the case in other London mental hospitals. He also took a deep and helpful interest in the work of the Mental After-Care Association for discharged patients, and he served on the council of that association.

Dr. Ogilvy was held in esteem and affection alike by his medical colleagues, his staff, and his patients. His devotion to duty, his sense of justice, his outspoken cheerfulness, endeared him to all who came into contact with him. No difference of opinion left one in doubt as to his genuine honesty of purpose. He was a candid friend to those who gained his confidence, and concealed beneath a certain genial bluntness of manner one was ever conscious of an essentially humane and lovable personality. All who knew him will desire to express their deepest sympathy with his widow and three children.

F. N. G. STARR, C.B.E., M.D., F.R.C.S.

Professor Emeritus of Clinical Surgery, Toronto; Vice-President, British Medical Association

Widespread regret has been expressed in this country at the loss sustained by general medicine, as well as surgery, in consequence of the death last month of Professor F. N. G. Starr after a week's illness. An outstanding diagnostician and surgeon, as well as a successful teacher and educational pioneer in the University of Toronto, he was also for many years a driving force in the development of the Canadian Medical Association.

Frederick Newton Gisborne Starr was born at Thorold in 1867, and received his early education in Ontario public and high schools, from whence he entered Victoria College, Toronto. In 1889 he graduated M.B., C.M., and subsequently proceeded M.D. After a long period of post-graduate work in England, France, and Germany he returned to Canada and commenced practice in Toronto. He became general secretary of the Canadian Medical Association in 1893, and held the post until 1901, remaining a member of its executive council, and holding the post of president in 1927. The influence of his wise guidance and stimulating encouragement was most marked; the inevitable difficulties of such an organization in the widely separated townships in a vast Dominion were steadily overcome, and the beneficent activities of the association were increasingly widely appreciated. The British Medical Association paid tribute to his devoted work and great success by electing him a vice-president.

His surgical skill was early apparent, and he held appointments at the Toronto General Hospital, the Toronto Western Hospital, the Hospital for Sick Children, St. John's Hospital, and the Women's Cottage Hospital. He was later appointed consulting surgeon to each of these institutions. He devoted himself also to the advancement of the growing University of Toronto, was a member of the board of governors, and held the rank of emeritus professor of clinical surgery. He was largely responsible for the founding of the Royal College of Physicians and Surgeons of Canada, was a councillor from 1907 to 1911, and was the first surgeon to become its president, a post he held from 1931 to 1933. He had been president of the Academy of Medicine, Toronto, in 1926. Very highly esteemed also in the United States, he was elected in 1932 a Fellow and first vice-president of the American Surgical Association. He was also a Fellow and past vice-president of the American College of Surgeons. With all his many obligations he never forsook his deep interest in student life: from its inauguration in Toronto he had been closely associated with the Nu Sigma Nu Medical Fraternity, and had acted as an adviser to the student members of the Toronto Chapter. He was also a member of the Alpha Omega Alpha Honor Medical Fraternity.

During the war Dr. Starr held a commission as major with the R.A.M.C. in France, and was twice mentioned

in dispatches. The C.B.E. was subsequently conferred upon him. He was a Fellow of the Royal Geographical Society. He retained an active interest in athletic and sporting pursuits, and was a member of two golf clubs, the Toronto Hunt and Jockey Clubs, the Royal Canadian Yacht Club, and the Royal Canadian Institute. He is survived by his widow and three brothers. His uncle, Frederic Newton Gisborne, was the originator and first manufacturer of the earliest submarine telegraph, and connected Cape Breton and Newfoundland by nearly ninety miles of cable.

The death of Dr. WILLIAM BROGDON PATERSON at his home at Aigburth on May 11th takes from Liverpool a practitioner who was widely known and respected by a large circle of colleagues, patients, and friends. For the last four years he had struggled against serious illness; and when, a few months ago, the inevitable end became clear to him and to those who were looking after him, he met it with quiet courage. He was born in 1865, his father being minister of Tranent, East Lothian. He was schooled in medicine at Edinburgh, where he qualified M.B., C.M. in 1887, afterwards becoming resident physician at the Cowgate Dispensary, Edinburgh. Later he came to Liverpool as house-surgeon to the Royal Southern Hospital. For some time he was medical officer to the Liverpool Medical Mission, and afterwards he became a partner of the late Dr. John Grimes of Grassendale, with whom he remained until 1903. Until a few years ago he was associated in partnership with Dr. H. R. Hurter of Cressington. His colleagues honoured him at various times by electing him first librarian and later vice-president of the Liverpool Medical Institution. His small stocky figure, with bright and kindly eyes shining from behind rather shaggy eyebrows, became well known to the men and women of all walks of life who made up the field of his large and widely extended family practice. His skill as a practitioner kept pace with the rapid advances of medicine, and to his professional duties he brought a discipline and integrity of purpose which left him with neither time nor inclination to waste words or energy on small talk or trivialities. At times life had hit him hard, but he emerged out of disappointment and sorrow to a fine sensitivity and sympathy, which was all the stronger for his reticence. His love of the beautiful in life brought him delight in art, in the engaging loveliness of children, and most of all in the contacts of his daily work. He possessed that austere sense of fitness and restraint which is associated with the classical Greek spirit, but with it were fused a serene kindness and an unusual power of feeling. A man's relations with children are a revealing touchstone of its quality; I had the intimate privilege of seeing how, busy as he was, he treated children with winning dignity and seriousness, so that they loved him and regretted he could not stay longer on his visits. I learned too his power not only of saying the right thing but of giving that rare sympathy which has an astringent and strengthening quality in it. He leaves a widow, whose comradeship and courage supported him always, especially in the last years. To her his colleagues offer their sympathy.

ROBERT COORE.

Dr. WILLIAM RUTHERFORD WOOD, who died at the age of 33, on May 17th, of septicaemia following the removal of tonsils, was one of the most promising of the younger practitioners in the Oxford district. The son of a medical man, he was educated at Queen Mary's Grammar School, Walsall, and after matriculation served with the R.F.C. during 1917 and 1918. After the war he went up to Pembroke College, Oxford, and in 1923 took second class honours in natural science (physiology). Proceeding to St. Thomas's Hospital, he qualified M.R.C.S., L.R.C.P. and B.M., B.Ch. in 1926, and completed his training with a year as resident at the Radcliffe Infirmary. He then entered general practice in Oxford. In 1929 he married Elmor, the daughter of Mr. and Mrs.

Smith-Hill of Braithwaite, Cumberland; she, with two daughters, survives him. Although never robust of physique, Wood enjoyed all outdoor pursuits, and was never happier than when boating or swimming in his beloved Thames, or floundering in Alpine snows to improve his considerable prowess on skis. He lies buried at Thornthwaite, surrounded by the hills which were his spiritual home. Shy by nature, and always diffident of his own powers, "Bill" Wood was no showman. Medicine has lost a conscientious servant, and humanity a loyal and sympathetic friend. H. N. B.

The death took place on May 23rd at his residence, 73, Murrayfield Gardens, Edinburgh, of Dr. H. C. GIBSON, who was well known in connexion with the neurological activities of the Ministry of Pensions. After a medical course at Edinburgh University, Hugh Craigie Gibson graduated M.B., C.M. in 1904. During the war he served as a major in the Royal Army Medical Corps, and after doing duty for some time at the Edinburgh War Hospital, Bangour, was placed in command of the special Neurological War Hospital at Glen Lomond Sanatorium. He afterwards became director of the Ministry of Pensions neurological clinic, Glasgow, and was attached to its neurological clinic in Edinburgh. Dr. Gibson was a member of the British Psychological Society and of the British Medical Association, which he joined in 1906.

We regret to announce the death, on May 16th, of Dr. RICHARD HENRY CYRIL GOMPERTZ of Barnstaple, at the age of 57. He was educated at Bedford Grammar School, King's College, London, and King's College Hospital, where he had a distinguished student career, gaining the junior and senior Clothworkers' scholarships and the Sambrooke scholarship. He obtained the M.R.C.S. and L.R.C.P. diplomas in 1904, and, after graduating in 1907 as B.Sc. M.B., B.S. (gold medal, with honours in medicine and surgery), was appointed demonstrator in physiology at King's College and surgical registrar to the hospital. He served throughout the war, mainly in France, with a temporary commission in the R.A.M.C., and was mentioned in dispatches. After a few years as medical officer to Berkhamsted School, Dr. Gompertz went to Barnstaple in 1923, joining a partnership there, and was appointed honorary medical officer to the North Devon Infirmary, with charge of the x-ray department. At Barnstaple he continued his close interest in the first-aid movement, and was medical officer to the local Voluntary Aid Detachment. Dr. Gompertz was a man with intellectual gifts beyond the ordinary, and found time to cultivate varied tastes outside the work of a busy general practitioner.

The following well-known foreign medical men have recently died: Dr. MAX VON KRYGER, emeritus professor of surgery, Erlangen, aged 72; San-Rat Dr. HANS AXMANN, an Erfurt dermatologist, aged 72; Dr. ANTON LIEVEN of Aix-la-Chapelle, a prominent syphilologist; Professor ROBERTO NOVOA SANTOS, professor of general pathology at Madrid, aged 49; Dr. FRANCISCO FABRÉGAS y MAS, ex-president of the Academy of Catalonia; Professor PIETRO LIGABUE, dean of the Faculty of Medicine of Florence; Professor THEODOR GÖTT, professor of children's diseases at Bonn, aged 53; Dr. RODRIGUEZ CADARZO, rector and professor of anatomy at the University of Santiago de Compostello; Dr. SCHREVE, formerly secretary of the Dutch Society of Medicine, aged 66; Dr. K. A. IORDINE, director of the ophthalmological clinic at Saratov University and organizer of the anti-trachoma institute on the Lower Volga; Dr. BOURSQUET, emeritus professor of surgery and director of the medical school at Clermont-Ferrand and national correspondent of the Académie de Médecine; Dr. HEINRICH HAEKE, extraordinary professor of cytology at Berlin, aged 70; and Geh. Rat Professor ALBERT SIEFEL, an eminent Frankfurt gynaecologist, aged 83.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

The House of Commons reassembled on May 29th and the House of Lords next day. The business of the week in the Commons included a debate on the Ministry of Education Estimates, and the committee stage of the money resolution relating to the milk marketing scheme.

On May 29th the Statutory Salaries Restoration Money Resolution was taken by the House of Commons in committee. Mr. Chamberlain, Chancellor of the Exchequer, in moving the resolution, said that abatements which were made in salaries and allowances in 1931 would be restored by one-half by administrative action where that was possible. Certain salaries, however, were fixed by statute, which required legislation to restore abatements. The resolution was moved to enable that legislation to be introduced; the first paragraph went further than was necessary to restore half the abatements made in 1931, and would authorize a Bill to restore the other and second portion of the abatements at some future time, if it was thought desirable to do so, without further legislation. The resolution was accepted.

Diphtheria and Enteric Inoculation in the Army.—On May 29th Mr. GROVES asked the Financial Secretary to the War Office if instructions of any kind had been issued to Army Medical Services or any other department of the Army in connexion with inoculation against diphtheria and enteric. Mr. DUFF COOPER replied in the affirmative. Immunization by means of protective inoculation against diphtheria and typhoid fever was on a voluntary basis in the Army. All ranks, with few exceptions, took advantage of these preventive measures in their own interests.

Fatal Road Accidents to Children.—On May 29th Sir HILTON YOUNG informed Mr. Groves that figures of the number of fatal accidents occasioned to children in the United Kingdom last year were not yet available. In 1932 the approximate number of persons in Great Britain under 15 who died as a result of accidents was 3,700. Of these deaths approximately 1,450 were due to road accidents. The other principal causes were burns and scalds, suffocation, drowning, falls, and inattention at birth.

Import Duty on Publications of Learned Societies.—On May 29th Captain CUNNINGHAM-REID asked if the Government would consider excluding from the operation of the Additional Import Duties (No. 6) Order, 1934, the publications of learned and scientific societies. Mr. HORE-BELISHA answered that this question was one in the first instance for the consideration of the Import Duties Advisory Committee, to whom representations should be made by the parties concerned.

Medical News

The Prosser White Oration before the St. John's Hospital Dermatological Society will be delivered by Dr. William Allen Pusey of Chicago on Wednesday, June 27th, at 5 p.m., at the Royal Society of Medicine, by permission of the president and council of the society. Dr. Pusey's subject will be "Disease, Gadfly of the Mind, Especially the Stimulus of Disease in the Development of the Mind."

Lord Moynihan will open the new private ward block of the East Suffolk and Ipswich Hospital, and the new ear, throat and nose, and x-ray departments, on Thursday, June 7th, at 3 p.m.

The Committee Against Malnutrition will hold a public meeting at 8 p.m. on Wednesday, June 13th, at 34, Red Lion Square, Southampton Row, W.C.1. The chair will be taken by Sir Frederick Gowland Hopkins, P.R.S., and Dr. Stella Churchill, Professor J. B. S. Haldane, Dr. R. D. Lawrence, and Dr. R. A. Lyster will be among

the speakers. Tickets (1s.) can be obtained from the honorary secretary, 19c, Eagle Street, Holborn, W.C.1.

A short course of lectures, on the approach to the psychoneuroses (for practitioners and medical students), will be given at the Institute of Medical Psychology, Malet Place, W.C., beginning June 18th. The fee for the course is £2.2s. for medical graduates and 10s. 6d. for medical students.

The British Waterworks Association will hold its twenty-third annual general meeting and conference in Edinburgh from June 26th to 30th. The subjects of "The Drought and its Lessons" and "Freshwater Biological Research and Water Supply" will be open for discussion arising out of the report of the Executive Committee, and papers will be read on "The Policy and Practice of Chlorination of Water Supplies," by Colonel P. S. Lelean, professor of public health, Edinburgh University, and on "Consumption, Misuse, and Waste of Water," by Mr. John Bowman.

The Joint Tuberculosis Council has arranged a post-graduate course, to be given by the medical and surgical staff of the Royal Chest Hospital, City Road, E.C., for one week from June 18th. The fee for the course is £3 3s. All inquiries should be addressed to the honorary secretary for post-graduate courses, Joint Tuberculosis Council, Pembury, The Drive, Rickmansworth, Herts.

The Fellowship of Medicine (1, Wimpole Street, W.1) announces further medical lectures at 11, Chandos Street, W., on June 5th and 12th, at 2.30 p.m.; also on June 9th, at 3 p.m., a surgical lecture-demonstration at the National Temperance Hospital. On June 9th and 10th there will be a week-end course in obstetrics at the City of London Maternity Hospital; from June 11th to June 23rd a course in medicine, surgery, and the specialties at the Prince of Wales's Hospital; and from June 11th to 16th a course in proctology at St. Mark's Hospital. Other forthcoming courses include cardiology at the National Heart Hospital, June 25th to July 7th; diseases of children at the Children's Clinic, June 25th to July 7th; ophthalmology at the Central London Ophthalmic Hospital, July 2nd to July 28th; a week-end course in medicine and surgery at the Metropolitan Hospital, June 30th and July 1st. Particulars are given each week in the diary column of our Supplement.

We are informed that the formal opening of the Voluntary Hospitals Conference by the Prince of Wales in the Guildhall on Wednesday, June 13th, will take place at 11.30 a.m., and not at 10 a.m. as previously announced.

A post-graduate course on tuberculosis will be held at the Hôpital Broussais, Paris, under the direction of Professor Émile Sergent, from June 11th to July 7th.

The National Birth Control Association (with which is incorporated the Birth Control Investigation Committee) has arranged a conference on birth control, for general nurses, public health workers, and midwives, to be held at the College of Nursing, Henrietta Street, London, W.1, on Friday, June 15th. At the morning session, with Lord Horder in the chair, Mr. Claude Mullins, metropolitan stipendiary magistrate, will lecture on "The Ethics of Birth Control," and Mrs. Stocks, J.P., on "Birth Control and the Public Health Service." In the afternoon, with Lady Denman in the chair, Dr. Helena Wright will lecture on "The Technique of Birth Control," and Mr. Cedric Lane-Roberts, F.R.C.S., on "The Contribution of the Nursing Profession." There will be time for discussion after each lecture. Tickets (price 2s. 6d.), admitting to both sessions, can be obtained from the secretary, N.B.C.A., 26, Eccleston Street, S.W.1.

The sixth international medical post-graduate course arranged by the Tomarkin Foundation will be held at St. Moritz (Grisons, Switzerland) from August 5th to 18th. The subject-matter to be dealt with is grouped over the following special branches: heart diseases, diseases of children, balneology, nutrition problems, gastro-intestinal diseases, and social medicine. Particulars may be had from the secretary, Tomarkin Foundation, Via Marco Minghetti 17, Rome.

The June number of *Great Thoughts* includes a well-informed and well-written article, over the signature "Note-Taker," on the public career of Sir Henry Brackenbury, Chairman of Council of the British Medical Association.

The ninth International Congress of Dermatology and Syphilology will be held at Budapest, under the presidency of Professor Louis Nekam, from September 15th to 21st, 1935. Dr. A. M. H. Gray of 69, Harley Street, W.1, the national secretary for this country, will be glad to receive short papers before the end of 1934, or at the latest by the end of January, 1935.

The twentieth International Congress on Alcoholism will be held at the Imperial Institute, South Kensington, from July 30th to August 3rd, under the presidency of Lord Astor. The aim of the congress is to secure a comprehensive world picture of the present position concerning alcoholism in its various ramifications in social life. Further information can be obtained from the convener, Dr. C. C. Weeks, 33, Bedford Place, W.C.2.

The annual congress known as the Journées Médicales Belges will be held in Brussels under the presidency of Professor Edgard Zunz from June 23rd to 27th, when the subject for discussion will be the physiology and pathology of the endocrine glands. The opening address will be delivered by Professor Loeper of Paris.

The London County Council, in an advertisement published this week, invites applications for the post of director of the radiological department of the Hammer-smith Hospital and British Post-Graduate School, Duane Road, W., and consulting radiologist to the Council's hospitals. The salary is £1,500 a year, and application forms, containing full particulars, may be obtained from the Clerk of the Council, County Hall, S.E.1, and are returnable by June 18th.

Dr. B. Holroyd of Pannal, near Harrogate, has, for the fourth successive year, been elected chairman of the Claro Guardians Committee of the West Riding County Council.

Professor Max Neuburger, having reached the age of 65, is retiring from the chair of medical history in the University of Vienna. He will continue his directorship of the Medico-Historical Institute.

The eightieth birthday of Professor Johann Horbaczewski, who was appointed the first Minister of Health in Austria in June, 1917, was celebrated on May 15th in the Ukrainian Free University of Prague. As a young assistant of Professor E. Ludwig in 1882 he had carried out the artificial preparation of uric acid.

Dr. John A. Hartwell has been nominated president of the New York Academy of Medicine.

Included in the will of the late Dr. Edward J. Cave of Bath, who left £49,679, is a bequest of £6,000 to St. Bartholomew's Hospital, London, for an entrance scholarship to be known as the "Helen Cave Memorial Scholarship."

The late Mr. Ernest White of Clanfield bequeathed £1,000 to the Radcliffe Infirmary, Oxford, to endow a bed to be used as far as may be for patients from Clanfield, and in the event of his net estate being more than £30,000, a further £1,000 to the Radcliffe Infirmary for general purposes. The net personalty of Mr. White's estate was £66,600.

The following appointments have recently been made in foreign faculties of medicine: Dr. L. Melanowski, professor of ophthalmology at Warsaw; Dr. Popoviciu, professor of physiology at Cluj, in succession to Professor Nitescu, who has been appointed to the chair of physiology at Bucarest; Dr. Max Baur, rector of Marburg University, professor of pharmacology at Frankfurt; Dr. Mario Aresi, professor of clinical medicine at Cagliari; and Dr. H. A. Tschernogabow, professor and director of the Dermatological Clinic of the Second University, Moscow, in succession to Professor Arthur Jordan.

The supplement to the *Paris Medical* of May 12th contains a complete list of the medical staff of the various Paris hospitals.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, Aitology Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westcent, London.

MEDICAL SECRETARY, Mediscera Westcent, London.

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 62580 Dublin), and of the Scottish Office, 7, Drumshough Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

? Bed-sore; Diagnosis Wanted

Dr. R. STEVENSON DOIG (Stornoway, Isle of Lewis) writes: I should be greatly obliged if some expert surgeon would give me his opinion on whether the condition described below is or is not a bed-sore. I had a woman in the hospital with an osteomyelitis of the symphysis pubis. This was operated upon on November 13th last after the patient—a very sturdy, well-built woman—had been in bed for a month. There was no sign of anything wrong with her back on the day of operation. However, the day after, when I turned her over on her face to allow the wound to drain, I discovered a red, inflamed area the size of my hand over the sacrum: it had a raised edge and a "root," while in the centre was an elliptical spot the size of a pigeon's egg, which was black and without sensation. Thinking of erysipelas, I painted around with iodine and applied ichthylol and glycerin over it. After two days serum oozed out, and the black portion began to separate. Hot boric fomentations were now applied, and two days later a huge slough came away right down to the sacrum, while pockets of pus were all around the central opening, and extended beneath the skin for two to three inches, and in parts a probe went in two and a half inches deep. The root was exquisitely tender. A bacteriological examination on December 2nd, 1933, revealed staphylococci. (The only organism present in the osteomyelitis was *B. coli*.) The lesion gradually became more widespread, and did not heal up until the beginning of April this year. The Wassermann reaction was negative. The opening was situated on the left buttock, but the undermining extended for three inches past the middle line to the right buttock. A surgeon who exposed the sacrum found it healthy. There has been divergence of opinion as to whether it was a bed-sore, and I would be grateful for help as to the nature of the initial condition in November.

Persistent Epistaxis

"W. D. C." (Alloa) has a patient who suffers from severe epistaxis. Examination of urine, blood pressure, heart, and blood has failed to reveal anything abnormal, and there is nothing in the nose of an unusual nature, though the mucous membrane is very congested. Local treatment has been tried—weak caustic, bland ointments, and cantery; internally, calcium lactate and ammonium carbonate have been given. The patient states that the condition came on after a prolonged period of nursing, with heavy lifting. "W. D. C." would like to know of any further treatment which might prove beneficial.

Wanted: G.P. Laboratory Equipment

"Q. R. S." asks for information as to the setting up of a cheap bacteriological laboratory in connexion with a surgery, and where such could be procured, as well as media, etc.

Pruritus Ani

Dr. CALEB JOYCE (Melbourne) writes, in answer to "M. O." in the *Journal* of March 3rd: I agree regarding diet as a cause; another cause is personal idiosyncrasy as to some article of food, the most important being the smear of faecal matter left after defaecation and imperfect cleansing by means of paper. I have found the solution of the trouble in many cases to consist in the use of a damp cloth following the use of paper.

"Oliguria"

Lieut.-Colonel EDWARD GOWLANDO, M.B. (Commandant, Star and Garter Home for Disabled Sailors and Soldiers, Richmond, Surrey), writes: There are under my care a number of cases of paraplegia following wounds of spine, etc., who occasionally have attacks similar to the patient described in Dr. Miles's letter—that is to say, the patients pass practically no urine for several days, and on catheterization a maximum amount of some 4 to 5 oz. is obtained during twenty-four hours. I have tried all ordinary remedies, but have come to the conclusion that nephritin tablets (Coates and Cooper) solve the difficulty more quickly and satisfactorily than any other treatment. These tablets are made of kidney substance and have to be given in large doses—namely, twenty to thirty tablets a day. The proof of the pudding is in the eating, and I can only say that all who have been treated in the way indicated frequently ask for a repetition of a course of these tablets when they find the amount of urine becoming scanty.

"R. B. G." writes, in answer to Dr. Miles in last week's issue (p. 972): Has he considered the possibility of his patient getting rid of her urine, secretly, in a hot-water bottle in the bathroom? I read of a somewhat similar case lately—I forget where, and in a nursing home to boot! But there is no end to deceptions, especially in a mental case like Dr. Miles's.

*Income Tax**Substitute During Leave*

"A. W. B." holds an appointment, and his council granted him leave for special study on condition that he provided a locumtenent. Can he deduct the cost—twenty-four guineas—in making his return?

** We fear not. If the council had granted him leave without pay and had provided the locumtenent, the position so far as "A. W. B." is concerned would have been similar in common sense but different in law. As it was he received the emoluments in full, and the question is whether he can claim that what he paid was expended in carrying out his duties. In fact they were incurred in enabling him to do something else, and do not seem to fall within the very restrictively defined scope of the deductions.

LETTERS, NOTES, ETC.

Fistula-in-ano

Dr. R. YOUNG KENNY (New Malden) writes: The aetiology of fistula-in-ano is briefly dismissed by nearly all authors of our surgical textbooks with practically the same words, which are so welcome to the medical student for examination purposes on account of the brevity of the statement—"fistula is always the result of abscess." One invites condemnation for ever questioning the accuracy of so useful and time-honoured a solution of the problem. I have been led to doubt the accuracy of this brief statement, and to place emphasis on the mechanism of rectal flatus as a primary aetiological factor. Observe what happens when a tyre with a weak outer cover is overcharged. The elastic lining bulges through the weak places. Thus, I think, is a picture of what occurs in the production of fistula. Near the sphincters, where general expansion is restricted, the gas pushes the elastic lining in the line of least resistance, and under the high pressure which sometimes obtains forms, at first, a dimple. High pressure recurs and the dimple deepens to a small crypt, and then to a fairly deep cul-de-sac. This advancing channel may be obstructed by a more resisting band of tissue and turned aside, or even made to branch in its course, following lines of least resistance. Such a channel may readily harbour infection which will produce an abscess or may go on growing till, under great strain and with much pain, it bursts to make an outlet. The practical reasons for bringing up this question are: that the treatment of fistula should commence before the fistula develops, and it takes it out of the domain of

the surgeon to that of the physician: provided the latter starts treatment in time. Since constipation with much gas is the aetiological factor, this must be treated and not neglected if fistula is to be prevented.

Planning a House for the Tropics

Engineer I. VICK, writing from Java to the *Arch. f. Schiffs- u. Tropen-Hygiene* last year, proposed a scheme for building in the Tropics the most comfortable sort of house. In the Tropics, it must be remembered, the sun will appear at every point of the compass at some time in the year, so that houses are much the same all round; there is not the difference between front and back that is seen at home, and their first function is to protect from sun and rain. The characters of the tropical climate are, he says, high temperature, high humidity, little cooling at night, and stillness of the air. Nowadays men make less money in the Tropics than formerly. Hence they have to live there longer than of old, and require all the better housing, while one of the great needs in their houses is ventilation to cool them. The author's first approximation to the ideal tropical home has a plan roughly square, a veranda at each end connected by a central lobby or hall through which there will generally be a draught, and on each side of it two square sleeping rooms, side by side, with a window on the outer wall. But in his final plan he has the good idea to turn the rooms of each pair outwards through half a right angle, thus making the house octagonal in plan, somewhat rosette-shaped. Thus he is able to put a window into each side wall of the room, and beyond the end wall is an annexe, containing the bathroom and latrine, which shelters the living room from the direct rays of the sun. These rooms in the Tropics should never measure less than 13 ft. by 13 ft., and 9½ ft. high (1,600 cubic feet). A damp-proof course should not be forgotten; the walls are to be of porous or honeycomb cement (itself an insulator), faced outside with white glazed tiles. The floor, too, is tiled, and there is a 3 ft. by 3 ft. opening in the ceiling, communicating with the space under the octagonal roof. This opening in the ceiling and the small ventilators under the windows are protected against insects by wire gauze, even if this does halve the effective apertures. The octagonal roof is of corrugated iron, and so the air under it is heated and escapes through louvres, being replaced by cooler air from the ventilators through the ceilings. To prevent the warm air under the roof from heating the rooms below it the ceilings are covered on the upper side with aluminium foil, cheap and lasting, and sure to reflect radiant heat. Sun-blinds hang from the eaves of the roof, so are never just in front of the windows, and do not impede ventilation.

Rapid Labour

Dr. ERIC KENDERDINE (Coventry) writes: I attended two rapid confinements last week, which seem of interest. A lady with her second baby began pains at 20.30 o'clock, the birth occurring at 20.55. The second case was a primipara. She had a hot bath on the Sunday at 23 o'clock, and noticed a slight "show." She went to bed and awoke at 1 o'clock. She defaecated normally, but "had to support herself in front." A feeling of weight at the rectum sent her in to see the nurse, sleeping in the next room, at 2.20, when the first real pain occurred. This made her stand first on one leg and then on the other. The nurse was surprised to see the head crowned, and hurried her on the bed, where birth took place at once. The patient then started laughing, as she did not think it could be so easy. Both of these mothers had calcium-vitamin therapy, and both babies were of normal size.

Medical Golf

The spring meeting of the Sussex Medical and Dental Golfing Society was held on the links of the West Sussex Golf Club on Sunday, May 27th. In the morning the competition for the Rolls-Hoare Cup, 18 holes medal play, was won by A. R. Ferguson, 74 - 2 = 72; C. Guy Whorlow, 92 - 15 = 77, being second. In the afternoon foursomes resulted in a tie at 1 up between H. Butcher and G. Thwaites, F. Graham Bonnalie and J. H. Raymond, and A. R. Ferguson and R. H. Barron.

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 41, 42, 43, 44, 45, 48, and 49 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 46 and 47.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 216.

PREVENTION OF PUERPERAL SEPSIS IN GENERAL PRACTICE*

BY

W. H. F. OXLEY, M.R.C.S., L.R.C.P., F.C.O.G.

HONORARY MEDICAL OFFICER AND LECTURER IN MIDWIFERY, EAST END MATERNITY HOSPITAL

In spite of the large amount of research work which has been undertaken and the numerous papers which have been written in the last ten years on the causation of puerperal sepsis, the position shows no improvement, but rather grows worse. Twenty years ago the death rate from puerperal sepsis was 1.42 per 1,000 live births; last year it was 1.61.¹

If we turn back to the days before the introduction of antiseptics into midwifery practice we find little upon which to congratulate ourselves. The Registrar-General's figures before the year 1892 are not quite comparable with those of to-day, since some of the maternal deaths from sepsis were entered under erysipelas and other septic diseases instead of under puerperal fever. Nevertheless, it is interesting to note that in 1862 the rate calculated from these returns was 1.3; in 1872, 1.8; and in 1882, 2.9. When the assignment of all deaths from puerperal sepsis to that heading was made there was a slight fall to 2.6. These figures at least suggest that the deaths from sepsis did not reach such an appalling height as we frequently suppose.

More reliable information has been presented to us by James Young,² who found from the records of the Edinburgh General Hospital that during the years 1826-57 the death rate from sepsis was 2 per 1,000. Further, most of the deaths occurred in epidemics, so that in some years there were large numbers and in others none at all. Collins reported that during his mastership of the Dublin Lying-in Hospital (1826-33) there were eighty-eight deaths from sepsis in the first three years and none at all in the last four, during which time 8,000 women had been delivered. The serious epidemics which broke out from time to time in all maternity hospitals, and which contributed so largely to the total number of deaths from sepsis, are now almost things of the past. The Departmental Committee on Maternal Mortality and Morbidity, which investigated the circumstances of 5,805 maternal deaths spread over a period of about three years, reported that

"the majority of deaths from sepsis seem to have occurred as isolated cases in the practice of an individual or hospital, and the committee has been unable to find any convincing evidence of direct spread from patient to patient as an important factor in maintaining the high and increasing death rate from puerperal fever."³

If the epidemics have disappeared and the death rate remains about the same, it follows that the number of deaths from isolated cases of puerperal sepsis has risen since the introduction of antiseptics into the practice of midwifery. That is in this country, but in the Scandinavian countries, which have not altered their statistical methods to any material extent during the last

fifty years, we find a definite drop synchronizing with the introduction of antiseptics.⁴ Thus in Denmark the puerperal sepsis death rate remained almost steady at 2.6 per 1,000 from 1856 until 1900-4, when it dropped to 1.5, and has since shown no tendency to rise.

Intervention in Normal Labour and Puerperal Sepsis

It would seem that the good effect of antiseptic precautions which is apparent in Scandinavia has been masked in this country by some change in our midwifery practice. Those of us who can look back forty years know that during that time there has been a great increase in obstetrical interference with the course of labour, and this is confirmed by the records of many hospitals. At Guy's Hospital in the years 1863-75 there was intervention in 1.35 per cent. of all labours, whereas in 1928 the rate was 18.6—fourteen times as much.⁵ Has any change in the women made this increase necessary? Rickety deformity of the pelvis is one of the commonest legitimate reasons for artificial intervention, yet it is very uncommon in London, and is probably less common now than fifty years ago. Women to-day are more anxious to have their labours terminated by forceps, but that applies far more to the upper than to the working classes. Is it not more likely that the change is in the doctors? Since the development of pelvic surgery few obstetricians limit their practice to obstetrics; they have all become operating gynaecologists, and I suggest that the surgical bias which this has given to their minds has swept them away from the sound foundations of midwifery laid down by Smellie and his successors. Their pupils, worried by the exigencies of private practice, have all too readily followed in their footsteps. Many general practitioners use forceps in 60 per cent. of their cases. Simpson found it necessary only once in 472.⁶

No similar increase of the intervention rate has occurred in the Scandinavian countries; in Utrecht, Holland, the forceps rate over a number of years was 0.6 per cent.; in Copenhagen, 0.8 per cent.; and in Gothenburg, Sweden, 0.4 per cent.; and the intervention for other reasons was also low. This is very significant, for Holland has the smallest death rate from sepsis in the world—namely, 0.99 per 1,000. (There is doubt as to the comparability of the figures from the other countries with our own.)

The close connexion between low intervention and low death rate from sepsis is pointed out by Munro Kerr.⁷ He picks out two London maternity hospitals as having almost reached the irreducible minimum for maternal deaths, and in both of them the forceps rate is under 3 per cent. Further light is thrown upon this question by the investigations of the Maternal Mortality Committee, which found that the number of deaths from sepsis after abnormal labour was equal to that following

* A British Medical Association Lecture delivered before the Mid-Cheshire Division on November 17th, 1933.

normal labour, although abnormal labours amount to only about 5 per cent. of the whole. The following table, compiled from a series of cases attended by the East End Maternity Hospital, shows an incidence of non-fatal sepsis over twenty times as high after abnormal as after normal labour.

	Confinements	Pyrexia	Percentage
Normal ...	8,010	15	0.18
Abnormal ...	476	20	4.20
	(5.6 per cent.)		

Consideration of all these points leads to the inevitable conclusion that a low sepsis rate in any practice depends upon success in securing spontaneous labour and in avoiding intervention.

Abnormal Labour Followed by Sepsis

It is of great practical importance to know the kind of abnormal condition which is likely to be followed by sepsis. In seven out of the twenty cases referred to above the hand was introduced into the uterus during or after the third stage of labour. This should be considered the most dangerous operation in the whole realm of midwifery, and should always be avoided if possible. There are three types of case in which it is commonly performed:

1. Cases in which the contraction and retraction of the uterus are unsatisfactory on account of the retention of small pieces of placenta or membranes; they can be much reduced in number by waiting patiently and allowing the uterus to expel the placenta into the vagina, instead of keeping up a continual massage of the uterus, which irritates it to contract before the whole of the placenta is separated.

2. Those in which, after the delivery of the child, there is such severe haemorrhage as to necessitate immediate manual removal of the placenta; they occur after prolonged labour, probably terminated by difficult forceps and chloroform anaesthesia, and can be avoided by careful examination and treatment before and during labour.

3. Cases in which the placenta is long retained without serious bleeding, and cannot be expressed by Credé's method; the injection of four ounces of glycerin into the umbilical vein will almost always cause a violent contraction of the uterus and expulsion of the placenta.

Ten of the twenty cases followed ante-partum haemorrhage, prolonged labour, or extensive trauma. Ante-partum haemorrhage cannot always be avoided, but the well-proved connexion between toxæmia and accidental haemorrhage, and the liability of placenta prævia to give rise to warning haemorrhages during the last few weeks of pregnancy, give us a guide to the steps which we may take towards their reduction. Prolonged labour and exhaustion are frequently due to disproportion between the head and the pelvis or to a posterior position, and can often be obviated by ante-natal care and attention during the first stage of labour, while the usual cause of severe trauma of the cervix and the vaginal walls is premature application of forceps. The ante-natal diagnosis of severe degrees of contraction is so easy that there is no excuse for unforeseen Caesarean sections late in labour, with their death rate of 265 per 1,000, mostly from sepsis.⁹ Forceps, used with proper antiseptic precautions merely to draw the head through the vulval orifice, do not increase the incidence of sepsis, and the only objection to their use for this purpose is that the very ease with which delivery can be accomplished is likely to lead to their misuse in cases which turn out to be difficult. We use them in only 2.6 per cent. of our cases.

Predisposing Factors

Although difficult to show by figures, it is within our knowledge that both chlorosis and pyelitis of pregnancy are factors predisposing to sepsis; toxæmia has no such connexion. A uterus left with placenta or blood clot

inside it must be guarded against, and free drainage must be encouraged by seeing that the mother moves about and is allowed to sit up in bed on the second day. It is almost universally stated that insanitary surroundings predispose to sepsis, but in a long series of normal cases we found that the incidence of septic infection was the same whether the confinement took place in hospital or in the slums. All serious abnormalities are brought into hospital because it is impossible to carry out the necessary obstetric treatment and nursing care in the poor homes of the patients.

I have been led to dwell upon the so-called predisposing causes of sepsis because by eradicating them general practitioners can halve their mortality from sepsis without even considering the bacteriological aspect of the subject. Trousseau,¹⁰ speaking of the causation of puerperal purulent infection in 1868, said: "Every disease has two elements; there is the cause, properly so called; and the state of the economy recipient of the morbid impression. These two elements are always present; the first to follow out its results; and the second to combat the cause." In the attempt to prevent the access of the first of these elements the second is often neglected, whereas both are of equal importance. Tissues, if healthy, can deal with a few pathogenic germs, or there would be no women alive to-day. I am convinced that the aim of the bacteriologists to prevent the access of germs to the genital canal from any source whatever is difficult, if not impossible, of attainment in actual practice, and that even if it be accomplished the germs which are always present in the vagina before labour begins, and which are harmless to healthy tissues, are able to attack those which have had their resistance lowered by the predisposing causes we have described. If not, why should a difficult forceps case, carried out under the strictest antiseptic ritual, so often become septic? The means which suffice to prevent sepsis after normal labour will not prevent it following abnormal labour.

Nothing I have said must be taken as implying that we may neglect antiseptic precautions, either in abnormal or normal labour; on the contrary, the fact that one-half the deaths from sepsis follow normal labour¹¹ shows that they are inadequate. I do not intend to enter into speculations from a bacteriological point of view as to what constitute adequate antiseptic precautions, for I am not competent to do so, but I will give an outline of those we use and the result we obtain, and draw what conclusions we may from them.

The routine is as follows. The patients in hospital are given a bath before labour. All are given an enema; the vulva is well washed with soap and water, the hair is clipped short with scissors, the vulva is re-washed, swabbed with clean water, and finally with perchloride of mercury 1 in 2,000. Attendants scrub their hands and forearms with soap and water, rinse in clean water, and scrub with perchloride of mercury 1 in 1,000. These processes are repeated frequently during labour, so that the hands of the attendants and the vulva of the patient are always damp with perchloride. Since the hospital is a training school, of necessity many vaginal examinations are made by the pupil midwives, but always under the direction of the sister in charge of the case. No gloves or masks are used. Silence or quiet speaking is enjoined in the labour ward, but I have no means of finding out whether this rule is observed in the absence of the doctor or matron. A douche is given after labour to hospital patients, again for teaching purposes, but not to those confined in their own homes. There is nothing new or startling in these precautions, but as they are made under supervision we know that they are carried out. It will be appreciated that for such a routine to be properly performed in private practice the help of a midwife or

trained nurse is necessary, and it is therefore important that the practice of attending midwifery cases without such help should be discontinued.

Now for the results. During the last ten years 20,705 cases were attended—12,505 in the hospital and 8,200 in their own homes. The number of deaths from sepsis was five, giving a rate of 0.24 per 1,000, and they all followed abnormal labour. As the number of cases and the time over which they were spread are more than sufficient to eliminate chance errors, we may fairly draw the following conclusions: (1) that death from endogenous infection after normal labour is an uncommon occurrence; (2) that the antiseptic precautions used were effective in preventing deaths from exogenous infection following normal labour; and (3) it is doubtful whether these measures are carried out to their full extent throughout England and Wales. The results also exemplify what I have already said, that measures which are effective in preventing death from sepsis after normal labour will not prevent it after abnormal labour.

In this series of cases there was no evidence of spray infection. This might have been a matter of chance, for none of our midwives might have been carriers of *Streptococcus haemolyticus*. To meet this possibility Dr. Leonard Colebrook examined swabs taken from the throat and nose of every pupil midwife when she began her month on the district. From October, 1932, to April, 1933, forty-five district pupils and sisters were examined, and haemolytic streptococci were found in five, which I am told is about the proportion in the general population. The first of these five wore a mask during her month, but the rest carried on their duties without special precautions. To discover if there was any streptococcal infection of our mothers a swab was taken from the cervix of every woman delivered between June, 1932, and May, 1933, who developed a temperature of 100° F. or more, unless a definite extragenital cause for the rise was found. One gave a positive result, but the throats were probably not the cause, for one of the children sleeping with the patient had impetigo, which, on culture, yielded a haemolytic streptococcus. Although typing failed to identify it, the presumption is that it was the source of the mother's infection. In view of this evidence it appears likely that the person who is usually stigmatized as a carrier is a perfectly harmless individual. At the same time, I am not prepared to say that anyone with active disease of the nose or throat is not a danger to the mothers, and as a matter of precaution we preclude any such person from practising midwifery until the disease has cleared up.

A few words are necessary upon our attitude towards gloves. We have tried them and found that they have certain disadvantages: (1) they are expensive; (2) the pupil midwives who wear them are unable to find out whether the os is fully dilated or the membranes ruptured, two very important practical points; and (3) the pupil midwives are inclined to be less careful in washing their hands, and find it difficult to manage the wrists of the gloves without getting them contaminated. I am also satisfied that doctors wearing gloves find it more difficult to perform intrauterine manipulations. For these reasons we have discarded their use, and our results show that we have not needed the added margin of safety that they are said to give. In my opinion it is probable that a simple routine such as has been described here will be more faithfully carried out than a more complicated one, and so in actual practice will ensure a greater degree of safety to a greater number of mothers.

We will now collect in the form of axioms the conclusions at which we have arrived, being confident that if general practitioners would base their methods of midwifery upon them they would effect a very definite

diminution in the number and the severity of their cases of puerperal sepsis.

Summary

1. A low sepsis rate in any practice depends upon success in securing spontaneous labour and in avoiding intervention.
2. Efficient care of the patient during pregnancy and labour will reduce the predisposing causes of sepsis to a minimum.
3. The practice of attending midwifery cases without the help of a trained midwife or nurse is dangerous, and should be discontinued.
4. A simple routine for antiseptic precautions is more likely to be faithfully carried out than a more complicated one, and so in actual practice will ensure a greater degree of safety to a greater number of mothers.

SOME OBSERVATIONS ON THE ACUTE ABDOMEN*

BY

T. G. ILLTYD JAMES, M.Ch., F.R.C.S.
CENTRAL MIDDLESEX COUNTY HOSPITAL

Acute abdominal conditions still loom largely on the horizon of medical practice. Their frequency does not appear to be abating, and the mortality rates of such examples as intestinal obstruction and perforated peptic ulcer still indicate the need for earlier treatment. In many instances a careful history and a complete clinical examination will indicate the correct diagnosis. Those conditions which may simulate an acute abdomen can usually be excluded, if the possibility of their occurrence is borne in mind and confirmatory evidence sought; such, for instance, as pneumonia with its referred pain, uraemia with its vomiting and abdominal distension, lead poisoning with its colic, or pregnancy and the various complications associated with it. Again, the history, the clinical signs, and an analysis of the character of the pain will usually serve to indicate those cases which do not necessitate an immediate operation—for example, renal or biliary colic.

The picture presented by many acute abdominal conditions necessitating urgent surgical treatment may be so typical that a diagnosis is readily made. Certain circumstances, however, may alter the local and general appearances and cause considerable difficulty. This paper is concerned with some of these conditions, and certain points in their diagnosis will be discussed.

The Influence of Old Age

The aged are subject to the same abdominal catastrophes that beset those of lesser years, and in many of them the manifestations may differ but little from those usually encountered. It is characteristic of old age, however, that the mental and physical response to stimuli tends to become sluggish, and this slow response is not

* Delivered to the Willesden Branch of the British Medical Association.

uncommonly illustrated by acute abdominal conditions of an inflammatory nature—notably acute appendicitis. Pain may not obtrude itself upon the patient until the local condition has advanced to the stage of peritonitis; the atrophied abdominal muscles may allow considerable distension to occur, but they are incapable of much rigidity, which is therefore slight or entirely absent. As one would expect, the temperature is often normal or but little raised, and constipation is usually present.

The senile patient thus frequently comes under observation late in the course of the malady, and the clinical picture is such that a diagnosis of intestinal obstruction may be made. One patient, a man of 80, suffering from appendicitis with peritonitis, presented such a marked degree of abdominal distension that a pre-operative diagnosis of volvulus of the sigmoid colon was made. It is not very uncommon for some of these patients to be submitted to operation—a blind caecostomy being intended for a supposed large bowel obstruction—but when the abdomen is opened appendicitis with peritonitis is found. At operation it is frequently discovered that a considerable degree of ptosis is present, the caecum and appendix being found in the pelvis. This may account, in part, for some of the anomalous features presented by these patients.

If the possibility of this departure from the normal is borne in mind confusion is less likely to occur. Tenderness over the lower abdomen and tenderness on rectal examination are seldom absent, and, as Lewin¹ has pointed out, the vomiting is much less than one would expect in an intestinal obstruction with a corresponding degree of distension. In any doubtful case auscultation of the abdomen and the radiological appearances would be valuable diagnostic aids. It is proposed to deal with these methods in detail later.

The sluggish response of the aged is again shown in the tendency to severe constipation, which not infrequently advances to the stage of faecal impaction with intestinal obstruction. Indeed, this is one of the commonest causes of obstructive symptoms in senile patients, and its importance lies in the ease with which the cause can be detected and removed.

Peritonitis Complicating Labour or Abortion

The peritonitis that may follow abortion or labour complicated by sepsis frequently presents anomalous features. It was not uncommon at operation for a large quantity of purulent fluid to be found in the peritoneal cavity when the clinical signs were but few. Abdominal pain may be only slight, and rigidity of the abdominal wall is often absent. No doubt the stress and strain on the abdominal muscles due to pregnancy and labour bring about an alteration of the usual reflexes, while the accompanying toxæmia or septicaemia will help to mask many of the local features.

In this type of peritonitis abdominal distension is frequently marked, and there is usually tenderness of the hypogastrium. Diarrhoea may be a prominent feature.² The preceding history, the temperature, and the character of the pulse will be useful guides. Pyrah and Oldfield,³ in an admirable survey of thirty-six cases, have shown that in sepsis following labour, so frequently streptococcal in nature, any abdominal pain and tenderness, especially if associated with abdominal distension, should be regarded with grave suspicion, for they usually indicate the presence of peritonitis. Similar features were presented by several cases of peritonitis following abortion that have come under observation. Abdominal pain and tenderness, however, were more prominent than in the preceding group, but rigidity of the abdominal wall was seldom a marked feature. The pallor presented by some of these patients was in keeping with the virulent nature of the infecting organism.

Perforation of Peptic Ulcers

Acute perforation of peptic ulcers is another condition that may cause difficulty in diagnosis. The typical features—the sudden onset of severe abdominal pain with prostration, and general rigidity and tenderness of the abdomen—are too well known to need amplification. But when the perforation is minute the picture may not be so clear, unless the case is seen early. This type is not uncommon, for, in the last eighty perforations observed, it has been present in six. It usually occurs when the stomach is empty and the small hole is rapidly covered by lymph.

The onset resembles the ordinary perforations, but the intensity of the pain may not be quite so severe; the initial signs and symptoms, however, rapidly abate, and become localized to the upper part or to the right side of the abdomen, simulating acute cholecystitis, acute appendicitis, or acute diseases of the chest. Shoulder pain, if present, or the absence of liver dullness, in conjunction with the local findings and the history of previous dyspeptic disturbance, would be strong presumptive evidence of the nature of the condition. In the absence of these helpful signs and symptoms, however, the diagnosis may be in doubt. The temperature in the early stages of perforated peptic ulcer is usually normal or subnormal, and this is a useful differential feature from acute affections of the chest. If the means are at hand, the demonstration of free gas in the peritoneal cavity by x-ray examination is conclusive evidence of perforation. It is possible, by means of a portable apparatus, to undertake this procedure with little or no discomfort to the patient.

The value of this method in a difficult case is illustrated in the following example. A male patient, aged 55, was brought to hospital five hours after the onset of acute abdominal pain, which had occurred in the City, and morphine had been given to relieve it. There was some tenderness and rigidity of the upper abdomen, but the clinical picture strongly suggested an early pneumonia; the respirations were rapid, shallow, and thoracic, and there were crepitations at the base of the right lung. An x-ray picture, however, revealed the typical sickle-shaped areas of free gas under the diaphragm, making the diagnosis of perforated peptic ulcer definite. Auscultation of the abdomen in this case presented absolute silence except for the transmission of heart sounds. When there is doubt this finding is strongly in favour of a perforation.

The Value of Auscultation

The stethoscope has long established itself as an indispensable aid in the diagnosis of diseases of the chest. Its use in acute abdominal conditions, however, is but little known and infrequently practised. In an obscure case its value may be very great. If we exclude those sounds associated with the pregnant uterus, and those sometimes transmitted when an organ like the stomach is distended, normally, on listening to any part of the abdomen, a medley of sounds is heard due to peristaltic activity. These sounds range from soft rustling noises to loud rumbling gurgles, and their number and variety may at first be confusing. Over the lower abdomen this confusion is less, and for practical purposes auscultation in this region suffices, concentrating on the sounds produced by the small intestine. It is the actual presence of these sounds rather than their nature that is important from the clinical point of view. After a little experience a certain amount of rhythm may be noted, the sounds rising and falling in intensity every ten or twenty seconds or so. It is advisable to listen for a few moments and to repeat the process, for the sounds may vary from time to time, often subsiding into silence to reappear in abundance.

It is clear that any mechanical obstruction causing retention of intestinal contents and increased peristalsis will lead to an augmentation in the number, the frequency, and the volume of these sounds; and, conversely, any condition diminishing peristaltic activity, such as paralytic ileus or peritonitis, will lead to a corresponding diminution. In intestinal obstruction the increase in the number and intensity of the sounds is easily elicited, and they give one the impression of metallic resonance in hollow caverns, often interspersed with loud and long gurgles as if gas were passing through narrow channels. They are very characteristic and, once heard, are readily recognized. In addition, the accumulation of fluid and gas often allows a splashing sound to be elicited when there is small-gut obstruction—by dipping the fingers quickly on the abdomen—a very useful sign when positive. These auscultatory signs are of most value in those cases of obstruction of the small intestine where little or no distension is present, not an uncommon finding in cases due to bands or adhesions.

In contrast with these findings we have the absolute silence presented by the abdomen in general peritonitis or paralytic ileus. Distension may be considerable in these conditions, and the clinical picture may resemble mechanical obstruction. Auscultation thus affords a ready means of differential diagnosis. A silent abdomen is also presented by most cases of perforation of the intestinal tract, even before peritonitis is established, but while peristaltic sounds are absent, transmitted heart sounds may sometimes be heard almost as loudly over the abdomen as over the praecordium. This sign was described long ago by Claybrook¹ as an indication of a rupture of the intestine following an abdominal injury. It may be positive, however, in any condition where there is a combination of free fluid and gas in the peritoneal cavity, and when elicited is suggestive of a perforation somewhere in the intestinal tract. These auscultatory signs have been found of considerable value in a doubtful case, and especially in atypical perforations of peptic ulcer. Abdominal auscultation may occasionally be of help in the differentiation from acute lesions of the chest, for in the latter conditions the sounds are rarely absent.

It is important to bear in mind that in acute inflammation of individual organs, such as the appendix or Fallopian tubes, so long as the inflammatory process remains confined to that particular viscus the sounds will be normal, perhaps a little diminished in their frequency and intensity. It is only when the inflammation becomes more general that the abdomen is reduced to silence. Confusion is not likely to arise from the coarse rubs that may sometimes be heard over inflamed organs like the gall-bladder; these are more readily detected by palpation.

To recapitulate, on auscultation of the abdomen it has been found that in mechanical obstruction of the intestine the number, the frequency, and the intensity of the normal peristaltic sounds are increased. General peritonitis and paralytic ileus reduce the abdomen to silence, while in perforations of the intestinal tract this peristaltic silence is frequently associated with the transmission of heart sounds, a combination of great diagnostic significance.

Radiology in Intestinal Obstruction

A method which often allows a definite diagnosis to be made in a suspected case of intestinal obstruction is that obtained by means of radiology. The mortality from obstruction is still high, and rises with each hour of delay. Earlier diagnosis and treatment are essential if mortality is to be reduced. The diagnosis may not be in doubt in many cases presenting typical features, for instance, the intussusception of children, strangulated external hernia,

or the acute obstruction that supervenes upon chronic occlusion of the large gut; but obstruction of the small intestine by bands or adhesions, especially those occurring soon after an abdominal operation, may present considerable difficulty. Distension of the abdomen is frequently absent in the early stages, and may be only slight even later if the obstruction is high.

It is particularly in this group that radiological evidence may be definite while clinical signs are equivocal. Radiological signs may be positive as early as two hours after the initial onset, and are earlier in strangulated than in simple obstructions.² This method, therefore, is useful as a complementary diagnostic aid to auscultation, when the means are at hand. No preparation is necessary, and there is no discomfort to the patient; if a portable apparatus is available the picture may be taken while he sits in bed. A lateral picture will often show a degree of distension much greater than that visible on clinical examination.

Under normal conditions in adults gas in demonstrable form is absent from the small intestine. In the large gut its presence is a matter of everyday observation. When obstruction occurs gas and fluid accumulate in the small gut, the junction of the two being shown by straight fluid levels in vertical or lateral radiographs, which are very characteristic. When the small intestine is affected the distended coils, with their feathered appearance, are readily seen, while gas is absent from the colon. Gas in the colon, in fact, would be strong evidence against obstruction of the small intestine.

By this method, therefore, it is possible to differentiate between obstruction of the large and of the small intestine, and in the former the exact site of the block may often be demonstrated by the abrupt termination of the gas shadow. This is of very great value in planning the type of operation. It will be seen that when the large intestine is involved the high gas columns are in marked contrast to the numerous shallow columns of small-gut obstructions. Paralytic ileus may present the same radiological features as mechanical obstruction, but the silence of the abdomen serves to differentiate this condition.

It is not to be inferred that radiology is necessary in the diagnosis of all acute obstructions; it is of value in the cases that are clinically doubtful; but even in those cases where the diagnosis is clear, a plain radiograph will often serve to demonstrate the site of the block.

W. A. Riley and C. H. Scheifley (*Journ. Amer. Med. Assoc.*, April 14th, 1934, p. 1217) maintain that trichinosis in man is far from rare in the United States, as a large number of serious cases come to the attention of the medical practitioner or pathologist, and a diagnosis of typhoid fever, rheumatism, or malaria is frequently made when the condition is really one of trichinosis. On examination of 117 cadavers at Minneapolis these writers found twenty cases of trichinosis in subjects who had never shown any symptoms of the disease. E. R. Pund and R. Mosteller (*ibid.*, p. 1220) report a fatal case of trichinosis in a negro boy, aged 11, who developed encephalitis three weeks after vaccination. There was no diarrhoea and no eosinophilia, but examination of the blood showed sickle-cell anaemia. Sections from the cortex, basal ganglia, medulla, and cerebellum showed minute inflammatory foci, in many of which embryos of *Trichina spiralis* were found.

POISONING BY CAUSTIC SODA

BY

STANLEY G. WILLIMOTT, PH.D. CANTAB. AND LIVERP.,
B.Sc.

GOVERNMENT ANALYST, CYPRUS

AND

MINNIE GOSDEN, M.B., B.S. LOND., D.T.M. AND H.
GOVERNMENT BACTERIOLOGIST, CYPRUS

(With Special Plate)

Fortunately poisoning by the fixed caustic alkalis is comparatively rare in England, although in Europe fatal cases appear to be not uncommon. Balázs,² for example, records in three years 754 alkali poisonings, of which 163, or 21.6 per cent., were fatal; and further statistics are given in the works of Popper¹ and Leschke.² In England ammonia is more frequently employed as a fatal poison, and, according to the Registrar-General's returns³ for the three years 1930 to 1932, it accounted for ninety-two deaths, of which seventy-eight were suicidal and the remainder accidental.

It is therefore somewhat remarkable that in a period covering little more than one year no fewer than eight cases of poisoning by caustic soda should have occurred in Cyprus, an island with a population of only 348,000. In England poisoning by the fixed alkalis has nearly always been the result of accident or negligence, and exceptionally of suicide, but in the cases in Cyprus, of which the available data are summarized in the table, half were accidental and half suicidal, the former occurring in children and the latter in adults. A number of typical cases of poisoning by caustic soda or caustic potash and their effects are discussed in the well-known works of Taylor,⁴ Glaister,⁵ and Wynter Blyth,⁶ so that little need be said here; while details of certain cases occurring in Central Europe are given in the texts of Popper and Leschke, already referred to. The majority of such cases appear to fall into two distinct groups: (a) those ending fatally within a few days, and (b) those ending fatally some months or years afterwards.⁴

Source of Caustic Soda

The use of caustic soda locally has greatly increased during the last few years, and it would appear that its misuse has increased correspondingly. Caustic soda is used in small quantities by the Cypriot community for domestic washing purposes, and is cheap and freely available. It has always been the practice in washing clothes to add some form of alkali in order to soften the generally prevailing hard waters of the plains of Cyprus. Formerly the alkali used consisted exclusively of wood ashes supplied from domestic sources. It is perhaps noteworthy that plant ashes, according to Mariti,⁷ were at one time produced in certain villages of Cyprus for export for industrial purposes. Within recent years, however, this has given place to washing soda ($\text{Na}_2\text{CO}_3 \cdot 10\text{H}_2\text{O}$), and during the last two or three years, in its turn, to caustic soda. The reasons given for this change are the cheapness and availability of caustic soda, and, it is claimed, the better results in the wash. In all these cases in Cyprus the alkali was obtained in this way, and its ready availability under the conditions prevailing constituted a serious problem. Practically the whole amount of the caustic soda imported from Europe is absorbed in the local soap industry, but, in view of recent experience, it was considered desirable to restrict its general domestic use. Accordingly it was advised that caustic soda and caustic potash should be placed on

the Poisons Schedule, and this recommendation was adopted by Government in February, 1934. A similar situation appears to have existed in Hungary,¹ where poisoning by caustic alkalis was common. There the difficulty was overcome in 1926 by subjecting the sale of caustic alkalis to restrictions.

The caustic soda as sold was in the form of broken fused lumps, and analysis showed an average content of 77 per cent. NaOH with 10 per cent. sodium carbonate. This latter impurity usually accompanies commercial grades. For washing purposes it is usual to dissolve about 50 grams in a little water, and to add this to about 120 litres of water.

General Features of Poisoning

In the table are summarized the available data of known cases of poisoning by caustic soda occurring since December, 1932, although there are possibly others unknown to the authorities. In spite of the difficulties of obtaining reliable data, especially in regard to the amount of alkali taken, it has been possible to study four of this series (Nos. 1, 4, 7, and 8), all affecting adults, in some detail. Starkenstein⁸ regards 10 to 20 grams of solid caustic alkali as the fatal dose, but it is clear from our own experience (see table) that a quantity less than 10 grams can be lethal. The fatal dose is unknown, but it is noteworthy that 2.6 grams (40 grains) of caustic potash have proved fatal (Taylor⁹).

Cases of Poisoning by Caustic Soda

Case	Patient	Age	Cause	Dose (grams)	Symptoms	Result
1	Turkish woman	33	Suicide	60	Burning pains in mouth, throat, and stomach; vomiting and exhaustion	Died 29½ hours after ingestion
2	Turkish child	1½	Accident	?	Lips, tongue, and palate burnt	Died 25 hours after ingestion
3	Greek child	3	Accident	Sucked a lump of NaOH	Mouth, lips, and tongue burnt	Recovery in 3 days
4	Turkish woman	20	Suicide	8.5	Burnings of mouth and palate; vomiting blood; shock	Died in 11 days
5	Turkish child	3	Accident	?	Oesophageal stricture; unable to swallow any liquid	Gastrostomy; recovering
6	Greek child	5	Accident	?	Emaciation; oesophageal stricture	Gastrostomy; died
7	Turkish girl	16	Suicide	5	Stricture of oesophagus and pylorus	Palliative jejunostomy. Died after 74 days
8	Turkish girl	15	Suicide	?	Burning of lips, tongue, pharynx; vomiting; shock	Died 26 hours after

The immediate effect of swallowing caustic alkali is to produce excoriation and destruction of the mucous membrane, which gives rise to intense pain, often extending from the mouth to the abdomen. The severity of the lesions depends upon the concentration of the alkali, the stomach contents, and the interval elapsing before treatment. Alkali corrosions are usually oedematous and unctuous as compared with those from acids, which are dry and hard. The alkali extracts water from the tissues with which it comes into contact, and attacks the protein, forming alkali-aluminate, which becomes gelatinous, swells, and in the presence of much water commences to dissolve—a process termed "colligation." Because of this, alkali burns penetrate deeply into the tissues, although cases of perforation are few compared with those which develop stricture later on.

Treatment follows the accepted lines of avoidance of stomach lavage, and the administration of organic acids and liquids in order to reduce the concentration of the alkali. The use of the bougie at the proper time is regarded as being very important, especially in Continental practice, in order to avoid later complications of oesophageal stricture.

Details of some Medical Cases

The first case of this series, which occurred in December, 1932, was one of determined suicide.

First Example.—A Turkish woman of Nicosia, a mother of five children, swallowed apparently no less than 60 grams (925 grains) of caustic soda dissolved in about 120 c.cm. of water. Symptoms of distress came on almost immediately, with vomiting and burning pains in the mouth, throat, and stomach, and with great exhaustion and collapse. It was observed that the buccal cavity, tonsils, and pharynx were soft and oedematous, and of the deep chocolate colour suggestive of recent burning by alkali, while the lips and tongue were red and swollen. The mouth gave a strong reaction to litmus paper, and the vomited matter consisted of a brownish liquid, due to the presence of blood, and contained portions of detached mucous membrane. This liquid gave a strongly alkaline reaction to litmus, which on analysis proved to be due to the presence of 1.6 per cent. of free caustic soda. The patient was allowed lemon juice *ad lib.*, but, although she appeared to have recovered from shock, her condition had deteriorated by next morning, and death took place twenty-nine and a half hours after ingestion of the poison. Unfortunately it was not possible to carry out a post-mortem examination, but it was considered that death had resulted probably from perforation of the stomach. A more detailed account of this case has been published elsewhere.⁸

Second Example.—The second case of interest (No. 4) again concerned a Turkish woman, a domestic servant, who, at 9 p.m. on August 31st, 1933, swallowed about 8.5 grams (123.4 grains) of caustic soda dissolved in a little water, to which had been added some rosewater in order to mask the burning taste. From the woman's statement the alkali had not completely dissolved, and apparently some was swallowed solid, a fact which may account for the oesophageal perforations found after death. The amount of caustic soda taken was more than three times the known fatal dose of caustic potash (40 grains).

The same symptoms as previously observed—that is, burning pains extending from the mouth to the stomach—came on immediately, with, later, vomiting of blood and mucus. On arrival at hospital, one and a half hours later, the patient was conscious, but suffering from shock, with the extremities very cold. Burning of the surface of the buccal cavity, however, was not so severe as that observed in the first case. Vomiting of blood persisted, and the vomitus gave a marked reaction to red litmus. The patient complained of severe pain in the throat and stomach. The temperature was 97° F., and the pulse rate 90, and during the eleven days of observation the temperature varied from 97° to 101°, the pulse rate between 84 and 130, and the respiration rate between 28 and 36. The patient recovered from shock, but swelling of the tissues which had been in contact with the alkali—especially the lips and tongue—was marked. By the fifth day the tongue was healing, though red, but no liquids could be swallowed, and feeding was carried out with liquid glucose per rectum. After the first week it was clear that the patient was not progressing, although the burned parts appeared to have healed, and to be covered with shiny mucous membrane. Later, signs of bronchopneumonia were observed, and the patient died on September 11th—that is, eleven days after swallowing the poison. In view of the amount of destruction of tissue in the oesophagus and stomach the length of survival appears remarkable. The coroner's finding at inquest was that death was due to exhaustion and bronchopneumonia resulting from suicide by swallowing corrosive poison.

Some interesting conditions were seen at necropsy, which was carried out five hours after death. Externally there were no unusual appearances. The lips were covered with smooth and somewhat shining mucous membrane, and the skin and mucous membranes were generally pale. Rigor mortis was present in all parts, and post-mortem staining in the dependent parts. The anterior half of the tongue was covered with smooth, shining mucous membrane, and at the back of the tongue the papillae were well marked. The mucous membrane in the upper part of the oesophagus was again smooth and shining, while the tip of the epiglottis was absent. At a point 9 cm. below the latter the walls of the

oesophagus were very soft and adherent to the vertebral bodies, and at this level an oval perforation, with smooth edges, 1.5 cm. long, was found between the oesophagus and the trachea. One centimetre below this there was a second circular perforation 1.1 cm. in diameter, also leading into the trachea (Fig. 1 on Special Plate). From the site of these perforations to the pylorus the mucous membrane of the oesophagus and stomach was very soft and pulpy, but the muscular wall was firm and intact. From the level of the lower perforation extending to the pylorus, a dark red, lightly adherent slough was found forming a complete cast of the oesophagus and stomach (Fig. 1 on Plate). The stomach was filled with a dark brown fluid, which gave an alkaline reaction. The mucous membrane of the duodenum was deeply injected, but below the pylorus there was no erosion. The trachea was filled with purulent material, and the left lung exhibited patches of aspiration bronchopneumonia. The liver showed cloudy swelling, and the kidneys were injected with pinpoint haemorrhages. Sections from the liver, kidney, and stomach near the cardiac end were prepared and examined. It was found that the stomach wall near the cardiac end exhibited remains of highly oedematous and necrotic mucous membrane, in which remnants of glands were recognizable. The muscular wall was little affected (Fig. 2 on Plate). Degeneration and desquamation of the tubular epithelium were seen in the kidney, with area of complete necrosis containing blood pigment (Fig. 3 on Plate). In the liver there were again areas of slight focal necrosis (Fig. 4 on Plate). The presence of such areas in the liver and kidney does not appear to have been observed in the recorded cases of poisoning by the fixed alkalis.

Third Example.—Case 8 was again one of suicide, in which a Turkish girl, aged 15, bought caustic soda, and made a concentrated solution with water. She swallowed a mouthful at 5.30 p.m. on April 2nd, 1934, and came to hospital an hour later vomiting and in a collapsed condition. She was treated by gastric lavage and lemon juice *ad lib.*, but swallowing was difficult and painful. During the next twenty-four hours there was a purulent exudate from the nose and mouth, increasing pulse rate, pain, and collapse, and death occurred twenty-six hours after taking the poison. A post-mortem examination, performed fifteen hours after death, showed burning of the tip and back of the tongue, the inner surface of the lips, and all over the tonsils and pharynx. The burnt areas were covered with a soft, brown slough. The oesophagus was deeply injected, but the mucous membrane was not eroded. In the stomach a burnt area, 15 cm. by 10 cm., and deep brown in colour, was found extending over the centre of the greater curvature. The mucous membrane was soft, but the wall of the stomach under the burnt area was firmer than the surrounding wall. The stomach contents consisted of a yellow fluid of slightly acid reaction. There was oedema of the lungs, but no consolidation. The liver exhibited cloudy swelling and the kidney congestion. The thymus was large and glandular, and all the lymphatic glands, especially in the neck, were large, soft, and dark red in colour.

Surgical Cases

The remainder consisted of a group of surgical cases under the care of Dr. C. H. Cuff, to whom we are indebted for certain clinical data. Stricture having developed, it was necessary to resort to gastrostomy in two instances and jejunostomy in another. It is interesting to note that stricture of the oesophagus was successfully treated by operation (gastrotomy), for the first time in 1885, by Loretta,¹¹ in the case of a patient of 24, who had swallowed caustic alkali. Since then surgical treatment had been resorted to with considerable benefit. In cases of non-malignant strictures of this nature, Grey Turner¹² has recently recorded striking success with the operation of oesophago-gastrostomy.

In the first of these cases (No. 6) gastrostomy, by Frank's method, was successfully performed, but the patient, aged 5, died the next day from peritonitis.

The second of this group (No. 5) was that of a Turkish girl, aged 3, who accidentally swallowed a little caustic soda solution on July 3rd, 1933, the exact amount being unknown.

The usual symptoms came on, and some burning of the face, lips, and tongue with oedema were observed on arrival at hospital shortly after. This appeared to be a mild case, and after two days the parents removed the child against medical advice. The subsequent history illustrates the necessity for continued observation and treatment in subjects which appear at first sight to be mild cases of alkali poisoning. On December 18th, 1933, the patient re-entered hospital unable to swallow any liquid, and it was impossible to pass any kind of sound through the stricture of the oesophagus which had developed. Radioscopic examination revealed oesophageal stenosis opposite the third costal cartilage, and gastrostomy was performed on December 21st. During three months the patient has made uninterrupted progress on a diet consisting of soup, eggs and milk, dried milk preparations, orange juice, etc., given at four-hourly intervals.

The last case of this group (No. 7) concerned a Turkish girl, aged 16, who attempted suicide on January 19th, 1934, by taking about 5 grams (77.2 grains) of strong caustic soda solution. On arrival at hospital within the hour the patient was suffering from shock, and complained of burning pain in the mouth and stomach. There was also purging and much vomiting of blood. The body temperature was subnormal, varying between 97° and 98° F. It was possible to pass a small sound, and lemon juice was given freely. The patient recovered from shock and appeared to be definitely improving when the relatives removed her after she had been one week in hospital. On February 12th she returned to hospital—this time unable to swallow even liquids—and was, in consequence, much emaciated. Radioscopy revealed a stricture of the oesophagus opposite the fifth costal cartilage. The patient continued to lose strength, and it was suspected that the pylorus also was stenosed. On operation this was found to be the case, and palliative jejunostomy was carried out (March 2nd). The patient was afterwards maintained on a diet of citrated milk, eggs, soup, meat extracts, olive oil, liquid glucose, etc., but the emaciation was progressive, and death took place on April 2nd.

Conclusions

Poisoning by caustic alkali in Cyprus has increased remarkably during the last year, and has justified Government action in restricting its free use for domestic purposes. In all the cases studied the poison was obtained in this way. Of these the suicides were among the adults and the accidental cases among the children. The fatal dose of caustic soda is less than 10 grams, and a quantity of 5 grams, in solution, has produced the most serious complications of stricture. There was perforation of the oesophagus in one fatal case, and possibly perforation of the stomach in another, while in another three cases stricture developed. Among the pathological conditions found post mortem, areas of necrosis in the liver and kidney have been observed (Case 4). It is evident from a study of these cases that the prognosis in alkali poisoning is doubtful, and that even in what appear to be mild cases the need for long-continued observation and treatment is essential.

We are indebted to Dr. C. H. Cuff, acting director of health, for permission to publish the results of this investigation.

IMPORTANCE OF LOCAL FACTORS IN THE ONSET OF PULMONARY TUBERCULOSIS

BY

W. PAGEL, M.D.

RESIDENT PATHOLOGIST, PAIOWORTH VILLAGE SETTLEMENT
(From the Laboratory of Papworth Village Settlement)

(With Special Plate)

The problem of the origin of recent tuberculous infiltrations of the lung ("Fruhinfiltrate," "Rundherde") is still unsolved. One group of authorities emphasizes exogenous reinfection, whereas other investigators direct their attention to the possibility of an endogenous development of the isolated pulmonary lesion of the adult. The importance of local factors in the location of recent tuberculous foci is perhaps not sufficiently recognized. Thus it may be of interest to publish the two following cases.

History of Case 1

The patient, a male aged 30, was in the Army (R.A.S.C.) for seven years, from 1922 to 1929. He was said to have been a heavy drinker until married. There was a family history of tuberculosis. The illness began with a gradual loss of weight and cough. For three months before admission there was blood staining of sputum and also morning vomiting.

POST-MORTEM EXAMINATION

Necropsy revealed carcinoma of the pancreas with metastases in the liver, spleen, kidneys, suprarenals, thyroid, right lung, and lymphatic glands all over the body.

Both upper lobes of the lung showed groups of miliary tubercles with areas of slight fibrosis and emphysema. The left lower lobe was normal, except for small groups of miliary tubercles at the apex and an old calcified focus in one of the lymphatic glands at the bifurcation of the bronchus. The right lower lobe contained a solid mass, of about the size of a tennis ball, close to the hilum: the tissue was firm and yellow, and resembled that of the enlarged mediastinal and abdominal lymphatic glands. The centre of this mass contained some anthracotic lymphatic glands with foci the size of a pea (carcinomatous metastases). Around the large mass was a group of small nodes with distinct walls, some of them liquefied (tuberculous foci) (Plate, Fig. 1). The pleura was thickened and adherent over the right lower lobe.

HISTOLOGICAL EXAMINATION

The tumour in the pancreas, and the secondary nodes in liver, spleen, suprarenals, kidneys, and lymph glands, showed on section solid carcinoma, partially adenocarcinoma.

In the upper lobe of the right lung there was fibrosis, with emphysema; proliferating tuberculous foci in the nature of miliary tubercles, rich in connective tissue and with many giant cells in various places; and caseous endarteritis of smaller vessels.

In the right lower lobe the big node close to the hilum was a solid carcinoma. In the foci surrounding this node caseous tissue with partial liquefaction was found. There were numerous tubercle bacilli in several foci, especially those made up of leucocytes; there were fewer bacilli in the large caseous foci.

Further examination revealed recent, partially liquefying, round tuberculous foci in this lobe. The foci resembled those described as early round infiltrations giving rise to the isolated pulmonary tuberculosis of the adult (so-called "Rundherde"). Such foci in a multiple form were first described by R. von Jaksch-Wartenhorst¹ as pseudo-tuberculous cysticercosis of the lung, later by Lachmann²—as atypical tuberculosis resembling tumour metastasis—and recently by Alb. Fraenkel,³ A. Albert,⁴ and Strauh. In this case these foci were found in one part of the lung only (the right lower lobe), where they occurred in the neighbourhood of a large carcinomatous metastasis. The pleura was thickened.

As regards other tuberculous foci there was a miliary distribution in both upper lobes, which were partially transformed into small fibrosing areas. No evidence was forthcoming to show that aspiration accounted for the recent infiltration in the right lower lobe.

Discussion

The condition of the lungs as a whole, and the presence of endarteritis in several vessels, point to the conclusion that the foci in the lower lobe were haematogenous tuberculous metastases. This was also suggested by the obvious haematogenous miliary tubercles in the upper lobes. Thus the case shows: (1) the haematogenous origin of recent tuberculous caseous circular foci of the lung; (2) a discrete spread of miliary tuberculosis preceding the development of the early caseous infiltrations; (3) that the distribution not only of miliary but also of larger caseous foci may be haemic in origin; (4) the importance of local conditions in the occurrence and growth of recent tuberculous foci; and (5) the difficulty of the differential diagnosis between carcinomatous and tuberculous infiltrations of the lung, both being present.

In this case there are two important features: (a) the presence of a large carcinomatous metastasis, by diminishing the resistance of certain areas, favoured the development of tuberculous foci from blood-borne tubercle bacilli; (b) the pleuritic thickening was probably responsible for the localization of the carcinomatous metastasis and so, indirectly, for the development of the recent adjacent tuberculous foci in this part of the lung.

History of Case II

The patient, a male aged 36, walked to a hospital outpatient department four days before death. X-ray examination disclosed a unilateral miliary condition of the lung. The patient died of bulbar paralysis.

POST-MORTEM EXAMINATION

Necropsy revealed a tuberculous meningitis, with some small conglomerate tubercles in the brain and cerebellum. There was also right-sided caseous epididymitis; caseous transformation of the right vesicular seminalis; caseous nodules in the right side of the prostate; and generalized miliary tuberculosis of the spleen, liver, and kidneys—especially the right. The left lung was adherent, with plastic fibrinous exudate over the pulmonary pleura: there were no miliary tubercles on the pleura, and no effusion. The right pleura, including the diaphragmatic reflection, was covered with miliary tubercles, which were also present in the right lung. The left lung was atelectatic, with a very few tubercles confined to the apex (Plate, Fig. 2).

HISTOLOGICAL EXAMINATION

There was an exudative meningitis of the brain, conglomerate tubercles being surrounded by plasma cells and lymphocytes, with an evident increase of connective tissue. Miliary tubercles, with many giant cells and proliferating connective tissue, were present in the spleen, liver, and lymphatic glands, with caseous centres only in the right lung (Plate, Fig. 3). A considerable number of tubercle bacilli were seen in all tissues examined. There was caseous proliferation of the thoracic duct.

In various sections of the left lung only one or two very small tubercles were found in the apical region, adjacent to the walls of a small vessel and differing from those in the right lung by containing nothing more than giant and epithelioid cells (Plate, Fig. 4). There was no sign of caseation or of tubercle bacilli. Chronic collapse of the alveoli, with fibrosis of the walls and thickening of the covering pleura, with scattered caseous foci and several giant cells, were also observed.

Discussion

This case of acute generalized miliary tuberculosis presents the following points of interest:

(a) The first is the extremely short clinical course (four days). An acute meningitis and cortico-encephalitis were

the cause of death, the fundamental miliary tuberculosis of the lung and the caseous tuberculosis of the urogenital organs being completely latent. From the histological picture, which showed numerous plasma cells and a considerable amount of connective tissue, the development of the tubercles in the brain must have commenced some weeks, if not months, before death. The fibrosis around the tuberculous foci in the spleen and lung suggests a lengthy duration of the miliary condition.

(b) The second point is the unilateral localization of the miliary outspread of the lung (involving difficulties in the clinical diagnosis); the freedom of one side of the chest from miliary tubercles was probably due to its chronic atelectatic condition, caused by an old and recent partially exudative pleurisy. The occurrence of unilateral miliary involvement of the lung was observed by Schmorl and Schottmüller,³ the latter of whom pointed out its importance as an indication for artificial pneumothorax. Artificial pneumothorax should therefore be performed not only in order to keep the present foci undisturbed, but also, in producing atelectasis, to prevent the formation of new foci. There is no doubt that changes in the condition of the blood circulation are responsible for such events; this is demonstrated by cases of syphilis of the pulmonary artery, in which there is unilateral contraction of its branches and tuberculosis is limited to the same side (Hebb,⁴ Pagel⁵), as well as by recent experimental observations (E. K. Wolff and Rob. Klopstock,⁶ A. F. Vorwald⁷).

Summary

The first case demonstrates the haematogenous development of the early tuberculous, caseous, circular infiltrations known as the introduction of the isolated pulmonary tuberculosis of adult life. ("Frühinfiltrate," "Rundherde"). Both these show the importance of local factors in the development and localization of tuberculous foci.

The Minister of Health, Sir Hilton Young, received a deputation on May 30th from the National Institute for the Deaf, the Counties Associations for the Deaf, the National College of Teachers of the Deaf, the Council of Church Missioners to the Deaf, and the British Deaf and Dumb Association. The deputation was introduced by Lord Charnwood, who spoke on behalf of all the societies represented. Their object was to suggest the necessity for legislation to make the welfare of the deaf the duty of local authorities, and to ask for the appointment of an advisory committee on the deaf. The Minister said in reply that he was in full sympathy with the desire of the deputation to promote the welfare of the deaf to the fullest possible extent. He believed, however, that progress was to be sought not in the imposition of compulsory duties on local authorities but in the encouragement of the work of these authorities and of voluntary agencies on the lines proposed in the circular on the subject issued by his Department (Circular 1337).

MALIGNANT TUMOURS OF THE KIDNEY AND TESTIS

BY

F. HECTOR SCOTSON, M.B., B.S., F.R.C.S.

HONORARY SURGEON, MANCHESTER VICTORIA MEMORIAL JEWISH
HOSPITAL; SURGICAL OFFICER TO OUT-PATIENTS,
MANCHESTER ROYAL INFIRMARY

(With Special Plate)

Malignant tumours of the kidney and testis are among the most interesting of all growths, both from a pathological and from a clinical point of view. Their importance lies in the marked degree of malignancy they show. In this communication I wish to draw attention to their pathology, and to record a case of an early hypernephroma of the kidney and of a seminoma of the testis.

Pathology of Malignant Disease of Kidney with Report of a Hypernephroma

The term "hypernephroma" (or Grawitz's tumour) implies an origin from the adrenal, but this conception is far from proved, and it is best to regard these tumours as renal carcinomas. The tumour has a well-marked tendency to invade and obstruct the renal pelvis, and so may produce a deformity which can be detected in a pyelogram. Microscopically their chief characteristics are their yellow colour, variegated appearance, and the frequent areas of haemorrhage. The cells are seen to be of large size, and the cytoplasm clear or slightly granular, due to the presence of lipid granules. The cells may be arranged in rows or may have an alveolar arrangement. Stroma is scanty but the blood vessels large.

The other type of malignant growth is the embryoma (or Wilm's tumour). This tumour, which appears generally between the first and third years of childhood, is at times bilateral. It is soft in consistency and of grey or yellow colour: on section it is uniform in appearance. Microscopically the appearance may resemble a sarcoma or a mixed tumour.

According to Boyd¹ all malignant growths of the kidney can be placed in one or other of the above groups, but other observers maintain that there is a renal carcinoma in addition to the true hypernephroma. Graham Simpson,² in recording three such cases, emphasizes the fact that such tumours replace rather than displace kidney tissue, so that, clinically, there is an absence of any marked enlargement of the affected kidney. In addition, the renal carcinoma is the more malignant neoplasm, in all his cases producing secondary deposits in, and destruction of, some of the bodies of the lumbar vertebrae.

CASE REPORT

A. B., aged 43, was operated on in 1917 for a right subphrenic abscess, which continued to drain for twelve weeks. He stated that since then he had always had pain in his back when he lifted anything heavy, but this was not more marked on one side than on the other. He said that the trouble had increased during the last two years. On September 15th, 1933, he was admitted to the Manchester Victoria Memorial Jewish Hospital on account of a severe attack of renal colic on the right side. Microscopical examination of the urine revealed the presence of red blood cells, although there was no macroscopic evidence of blood. An x-ray of the urinary tract did not reveal any evidence of stone. After the injection of intravenous uroselectan a further x-ray revealed a normal appearance of the pelvis of the left kidney, but on the right side, instead of a uniform density as on the left side, the upper part of the shadow was extremely dense and somewhat enlarged.

Cystoscopy showed that the bladder and ureteric orifices were normal. Indigo-carmin, injected intravenously, was excreted by both kidneys in the average time and with equal force, the efflux from the right kidney appearing to be as

deeply coloured as that from the left. Using 12½ per cent. sodium iodide through the ureteric catheter, a pyelogram was made of the pelvis of the right kidney. The resulting pyelogram was identical in appearance to that presented by the intravenous uroselectan. The interpretation of the pyelogram was not clear, but it was suggested that such an appearance might be due to a stone which was not radio-opaque, or to a small growth obstructing the pelvis of the kidney. It was therefore decided to explore the affected kidney.

On October 4th, through a lumbar incision, the right kidney was exposed. Externally, no evidence of disease was found, and so a small incision was made into the convex margin of the kidney in order to explore it digitally, but this did not reveal anything abnormal. Bearing in mind the possibility of a small growth in the kidney, this organ was then excised. This turned out to be a difficult operation on account of the dense adhesions present, resulting from the former perinephritic abscess. Convalescence was uneventful, and the patient returned to his work as an engineer in two months' time.

Pathological Specimen.—On cutting the kidney longitudinally from the outer to the inner border, a small tumour was revealed. Macroscopically and microscopically this had the appearance of a hypernephroma. This growth obstructed the upper part of the pelvis, producing a dilated and thickened upper compartment, which explained the appearance presented by the pyelogram, due to the large collection of radio-opaque material which would collect in it.

The special points of interest in the case are the very small size of the growth and the unusual appearance presented by the pyelogram. The photographs (reproduced on the Plate) show: Fig. 1, the specimen removed; Fig. 2, microphotograph of tumour showing typical appearance of the hypernephroma.

Pathology of Malignant Disease of Testis with Report of a Seminoma

The modern conception of tumours of the testis is a simple one when compared to the old complicated classification. They are now generally placed in one of two groups: first, the germinal cell tumour, or seminoma,¹ and secondly, the teratoma. The seminoma seems to arise from the cells lining the seminiferous tubules. The tumour appears in middle life, and is of comparatively slow growth. On section the tumour is seen to be solid, fleshy, and homogeneous, often traversed by fibrous septa, which cause a lobulated appearance. The microscopical appearance varies, the cells being of either large size, with clear protoplasm; or small size, containing a darkly staining nucleus, giving rise to a picture like that of lympho-sarcoma. A tubular arrangement may be apparent in the slow-growing tumours, or else a diffuse arrangement.

A teratoma probably arises from the primitive germinal cells, which, being totipotent, produce structures derived from all three primitive layers. It presents, as a rule, a markedly cystic appearance, but parts or the whole of the tumour may be solid. Microscopically, derivations of all three germinal layers may be seen in varying proportions.

CASE REPORT

T. W., aged 57, complained of a painless swelling of the right testis, starting six months previously. There had been a gradual increase in size of the affected testis since the onset. There was no history of gonorrhoea, tuberculosis, or other infection. Examination showed that the body of the right testicle was enlarged to about four times its ordinary size, and, in addition, the globus major of the epididymis was markedly bigger than normal. The organ was not tender. Rectal examination did not reveal any abnormality of the prostate gland or vesiculae seminales. A provisional diagnosis of tuberculous epididymitis was made, and, as the disease seemed entirely confined to the one testis, operation was advised.

When the testis was exposed the body seemed very hard, and neoplasm was then suspected; the whole testis was therefore excised, together with the spermatic cord, as far as the internal abdominal ring. On cutting the testis longitudinally a neoplasm infiltrating the body and also appearing in the epididymis was seen. The lumbar lymphatic glands were not

excised, but, as soon as the operation wound was healed, these were treated with x rays. Unfortunately this patient has been lost sight of, and has not continued to attend for the x-ray treatment or replied to recent communications.

Pathological Specimen.—The report, made by Dr. William Susman, stated that the microscopical appearance was typical of a seminoma. The growth was somewhat necrotic and very cellular, with scanty stroma. The cells were large and spheroidal, showing no conspicuous amount of mitotic division. Judging by the microscopical appearance the pathologist considered the growth to be undoubtedly malignant, but there

was nothing to indicate whether or not it was rapidly growing. The photographs (reproduced on the Plate) show: Fig. 3, the affected testis divided longitudinally; and Fig. 4, micro-photograph of the neoplasm.

My thanks are due to Dr. S. Kelly, who called me into consultation respecting the case of hypernephroma; to Dr. H. Morris, for the x-ray reports; and to Mr. J. B. Macalpine, who kindly gave advice on the interpretation of these.

GIANT RENAL CALCULUS

BY

WILLIAM EVERETT, M.B., F.R.C.S.ED.

HONORARY SURGEON, ROYAL HANTS COUNTY HOSPITAL, WINCHESTER

(With Special Plate)

It is unusual to observe giant renal calculi, so that the case here recorded would merit a report. The largest renal calculus in the museum of the Royal College of Surgeons of England was successfully removed from a male at operation by Mr. Hurry Fenwick in 1912, and weighed 1 lb. 9½ oz. The largest in the museum of the Royal College of Surgeons of Edinburgh weighs 1 lb. 9 oz., and was successfully removed, also from a male.

Marmaduke Shields reports the removal of a stone 1 lb. 0½ oz. in weight from a male aged 39. He states that there is an enormous stone weighing 2 lb. 0½ oz. in the museum of St. Bartholomew's Hospital, which was removed from a man aged 38. Thomson - Walker mentions that LeDenti reported a stone weighing over 3 lb., but whether this was removed at operation or necropsy is not stated. Kreutzmann reports the removal of a stone weighing 650 grams (circ. 1 lb. 7 oz.), and under a careful review of the literature states that the largest single stone removed at operation was reported by Mylvaganam, and weighed 3 lb. Kreutzmann quotes eight cases of unusually large renal calculi, the smallest stone weighing 339 grams (circ. 12 oz.), occurring in the only female in the series. Waterworth, in 1932, reported a stone weighing 2.42 lb. associated with carcinoma of the same kidney.

Clinical Case Record

A woman, aged 59, was admitted to the Royal Hants County Hospital, Winchester, on November 1st, 1933, complaining of a mass in the right side of the abdomen, accompanied by pain.

History of Illness

The date of the onset was given as in November, 1929. At that time the patient went to a doctor complaining of

an aching pain in the back accompanied by scalding micturition, and the passing of blood-stained urine. She was treated by her doctor, and the pain and urinary disturbance passed off, and for twelve months thereafter there was no complaint. In November, 1932, however, the aching pain in the right loin and right hypochondrium recurred occasionally, and was worse after a day's hard work. When examined upon admission to hospital there was no complaint of any urinary disturbance, but the patient stated that she had lost her appetite and had been losing weight during the last twelve months. The pain had never been of an acute character, and she was always able to continue with her household duties. She had had no colic or rigors. She had borne eleven children, and her pregnancies had been uncomplicated.

Physical Examination

On admission to hospital the patient was an ill-nourished, spare woman. Her extremities were cold and blue; her pulse was 100, and was small and of very low tension; her respiration was 20, and her temperature 97°. Her condition was one of advancing uraemia. There was marked oral sepsis and dental caries, and the tongue was dry and glazed. Examination of the heart and lungs failed to reveal any evidence of disease. Blood pressure was 100/50. On inspection, the abdomen showed a large bulging mass in the right side extending

from the right iliac fossa up underneath the right costal margin. The medial margin of the tumour crossed the mid-line in the epigastrium for about an inch, and the mass could be seen to move upon respiration when the patient was recumbent. On palpation the large mass was found to be slightly nodular, and two hard projections could be felt in the right iliac fossa. The whole tumour was tender, but tenderness was most acute over the projections at its lower end.

The specific gravity of the urine was 1020; it contained no sugar, but blood, albumin, and pus were present. The amount recorded during the day varied from 16 to 36 ounces. Many white and red blood cells were present. The blood urea equalled 355 mg. per 100 c.cm. nine days before death.

X-ray examination revealed on the right side a large, branched calculus with an ovoid central portion filling the pelvis. The left kidney also contained multiple calculi. Examination of the renal function with uroselectan showed no urine coming from the left kidney, and demonstrated a small amount in the right pelvic ureter after thirty-five minutes.

Operative treatment was out of the question, and the patient died on the sixteenth day after admission to hospital,

the cause of death being uraemia following bilateral calculous pyonephrosis. Only on the second and third days did the temperature rise above the normal, when in the evenings it was 100° and 102° respectively.

Post-mortem Examination: Abdomen only

Both kidneys were removed; the right one measured 9 inches long, 7 inches broad, and 5 inches thick, and weighed 4 lb., while the left one weighed 12 oz. The left kidney showed many hydronephrotic sacs with very little renal substance, and contained multiple calculi. The right kidney contained a large stone, and showed a scar on its anterior aspect in the region of fracture of one of the branches of the stone where probable ulceration had previously taken place. This kidney also contained many hydronephrotic sacs, and upon opening these urine and thick sanious pus were found. Outside the renal pelvis the kidney substance was replaced by fibro-fatty material, which was 1½ inches thick in some places. In the right kidney were found one large branched calculus weighing 1 lb. 3¼ oz., and two rough portions which had evidently broken off at a former date. There was very little renal substance left, and this was infiltrated with multiple abscesses. Three polished stones were lying in one of the cavities. The gall-bladder was normal and contained no calculi; other organs showed no abnormalities. The total weight of the calculi immediately after removal from the right kidney was 1 lb. 6 oz.

Description of Stone

The stone is composed of a solid central portion, ovoid in shape, which presents at its lower aspect definite curved indentations, where it has impinged against the vertebrae and transverse spinal processes. There is also a flattened area, where it has pressed against a vertebra. The length of the central portion is 4 inches, its transverse circumference 9 inches, and its vertical circumference 9½ inches. At its lower pole is one trunk breaking up into four branches. From the central portion posteriorly are two small horns, and anteriorly a long thin branch about 2 inches long, from which, obviously, one of the free portions of stone has broken away (See Plate). At the upper end, attached to one trunk, are again four branches. The longitudinal circumference of the entire stone is 18 inches.

Remarks

As is so often reported in cases of large stone there had been little or no disability in spite of a duration of many years. The case is interesting in that the calculus formed a large visible and palpable tumour in the right side. It would appear that giant renal calculus is more common in the male, and that probably this stone is the largest yet recorded taken from the female kidney.

The case was sent to me by Dr. Léonard Oliver of Ropley, Hants.

RADIOGRAPHY OF CALCIFICATION IN CARDIAC VALVES DURING LIFE

BY

J. V. SPARKS, B.A., M.R.C.S., D.M.R.E.
CHIEF ASSISTANT, X-RAY DEPARTMENT, ST. BARTHOLOMEW'S HOSPITAL;
RADIOLOGIST, CITY OF LONDON CHIEF HOSPITAL

AND

COURTENAY EVANS, M.D., M.R.C.P.

CHIEF ASSISTANT, A MEDICAL UNIT, ST. BARTHOLOMEW'S HOSPITAL

(With Special Plate)

Following the description in 1933 by Sosman and Wosika,¹ and Bishop and Roesler,² of calcification in the cardiac valves, we have attempted to demonstrate these calcifications radioscopically. One of us (C. E.) selected clinical cases which were likely to show these calcifications, and they were revealed in the first case examined. The clinical and radiological findings are briefly described, together with the radiographic technique used to demonstrate such a lesion.

History of Case

A married woman, aged 52 years, had for twenty months complained of pain in the sternal region, which occurred chiefly on hurrying, and very occasionally when sitting still. There was giddiness on sitting up suddenly or stooping; and sometimes shortness of breath. There was no history of rheumatism or growing pains.

Clinical Findings

The patient was a little cyanosed, and not obviously short of breath. The heart was enlarged slightly, the apex being in the fifth space in the mid-clavicular line, the impulse being heaving. There was a systolic thrill in the second right intercostal space. On auscultation an apical systolic murmur was conducted to the axilla, and the second sound was followed by a faint diastolic murmur. At the aortic base a systolic murmur was present and was conducted into the neck; along the left border of the sternum there was a faint diastolic murmur. The pulse had a frequency of 68, the rhythm was regular, and the wave had a slow rise and fall. The radial and brachial arteries were thickened. The blood pressure was 170/130 mm. Hg. The remainder of the physical examination was negative. The blood Wassermann reaction was negative, and the electrocardiogram was physiological. The diagnosis was aortic stenosis with arteriosclerosis and hypertension.

X-Ray Findings

Fluoroscopy revealed that the heart was centrally placed, and the mediastinal shadow considerably widened; the widening was thought to be due to enlargement of the aortic arch. On rotation of the patient into the semi-oblique position a well-marked comma-shaped area of calcification was visible in the position of the aortic valve. The movement of this shadow was considerable: it was more fixed at the upper end, and showed a jerking movement somewhat similar to that of a pendulum, the lower margin moving about a centimetre at each impulse. The movement was mainly backwards and to the patient's right. The shadow could be seen in both the right and the left oblique positions, and was very clear in the left lateral position, the convexity being forwards. The radiograms indicate the central position of the heart and the position of the calcified area in the anterior right semi-oblique and left semi-oblique positions (see Special Plate).

Radiographic Technique

It was pointed out by Sosman that it was remarkable that the means for the demonstration of these lesions had been available for at least thirty years, and that this possibility had only just been recognized, for the calcifications can be observed readily on the screen, provided that the eyes are adequately adapted, and that the screen examination is made

with a sufficiently small diaphragm. We have, in addition, the advantage of using a new Levy screen, which has three times the brightness of an ordinary fluorescent screen, and the contrast is made by screening through the Lysholm grid. The radiographic demonstration of such lesions is naturally more difficult, and will vary with the power of the apparatus available, the object being to obtain the shortest possible exposure, so that the view may be taken without any blurring from cardiac movement. The ideal will naturally be obtained by using very high milliamperage with a suitable small cone. The radiographs submitted were taken with only 100 mA and 1/25 of a second exposure by reducing the focal film distance to twenty-four inches, but there may be advantages in employing 1,000 mA and 1/100 of a second exposure if such a powerful apparatus, which is already on the market, is available.

Significance of Calcification in Heart Valves

Calcification in the heart valves may be present as the nodular type described by Monckéberg,² a condition of subendocardial calcification in the aortic valve occurring in middle or old age, and of doubtful relation to atheroma. Calcification to a lesser degree is associated with atheroma and as a result of valvulitis—rheumatic, subacute bacterial, or syphilitic. In the nodular calcified group the portion of the valve near the aortic attachment is affected; disease of the adjoining aorta is usually absent. In atheroma the attached portion of the valve is most likely to be calcified, while in rheumatic valvulitis the free edge of the valve would contain the calcium deposits. In subacute bacterial endocarditis bizarre areas of calcification are not uncommonly seen. Calcification of the aortic valve and atheroma of the aorta would indicate disease of the mouths of the coronary arteries and the possibility of occlusion. In rheumatic endocarditis valvular calcification would be evidence of local healing; and in subacute bacterial endocarditis the calcium deposits would show that the body was making an effort to combat the disease. (It would be particularly interesting to examine by this new technique patients who are stated to have recovered from this disease.) In syphilitic heart disease calcium deposit would suggest the coexistence of atheroma.

The presence of a landmark within the heart will be of assistance in giving anatomical significance to radiographic findings. Both coronary arteries arise from the sinuses of Valsalva of the aortic valve, and it may be possible to map out the usual distribution of the arteries and to localize small areas of calcification as being in the course of these vessels. (We are carrying out experiments on post-mortem specimens along these lines.)

We are indebted to Dr. Geoffrey Evans for permission to publish this case, and to Dr. Finzi for allowing us to reproduce the radiograms, which were taken in the x-ray department at St. Bartholomew's Hospital.

The first issue for 1934 of *The Fight Against Disease*, the quarterly journal of the Research Defence Society, contains an account of the debates held in the Universities of Manchester and Glasgow. In each case the voting went heavily against the supporters of antivivisection. Sir Leonard Rogers spoke on both occasions, and instanced the many advances in therapy which had been rendered possible by animal experiments. The issue also contains an account of the research regulations in Germany, the prevention and cure of certain common diseases of animals, and a critical examination of recent antivivisection and antivivisection propaganda. Professor Edward Mellinby has become a vice-president of the Research Defence Society and a member of the general committee.

A CONTRIBUTION TO THE CHOICE OF ANAESTHETIC

BY

PAUL KUHNE, M.D. LAUS., M.M.S.A.

HONORARY ANAESTHETIST, BUCHANAN HOSPITAL, ST. LEONARDS-ON-SEA

In view of the prevalence of new forms of general anaesthesia the case to be described below should prove of interest. The patient was under the care of Mr. D. Ligat in the ear, nose, and throat department of the Buchanan Hospital, St. Leonards-on-Sea, and had treatment which necessitated four general anaesthetics within a period of thirty-one days. She was given a different type of general anaesthetic on each occasion, and in my opinion a description of their effects from the surgeon's, patient's, and anaesthetist's point of view should prove helpful.

The following anaesthetics were used in the order given: (1) chloroform and ether; (3) sodium evipan; (3) avertin with gas and oxygen; (4) evipan with premedication.

Case Record

The patient, a single woman aged 31 (weight 9 st. 6½ lb.), gave a history of chronic otorrhoea of left ear since an attack of scarlet fever at the age of 10. She was admitted for persistent otorrhoea, deafness, and tenderness over the left mastoid. On examination nothing abnormal was found apart from the ear trouble. The blood pressure was 130/70.

First Operation.—Two days after admission a radical mastoid operation was performed under chloroform and ether anaesthesia with a preoperative injection of 1/100 grain of atropine sulphate. The patient was induced with C.E., after which the percentage of chloroform was gradually reduced to about 10. The anaesthetic was administered for one and a half hours. The temperatures and pulse rates before and after the operation and twenty-four hours later were respectively 97.4° and 68, 98° and 90, and 99.6° and 88. The patient was very sick for twenty-four hours, and complained of nausea for three days.

Second Operation.—Four days after the operation the wound was redressed under evipan anaesthesia. Eight c.c.m. of the standard solution of sodium evipan was injected intravenously in one and a half minutes (the first 4 c.c.m. in one minute). Complete anaesthesia, lasting ten minutes, was obtained. The temperatures and pulse rates, as above, were respectively 98.6° and 78, 98.8° and 84, and 98.6° and 86. The patient complained of slight headache the next day.

Third Operation.—Twenty days after the first operation two Thiertsch's grafts were applied to the ear cavity under avertin and gas-and-oxygen anaesthesia. One hundred minims of avertin dissolved in 8½ oz. of distilled water at 40°C. were given rectally forty minutes before admission to the theatre. A nasal intratracheal tube was introduced under gas and oxygen, which was administered for thirty minutes. The temperatures and pulse rates, as above, were respectively 98° and 80, 98° and 78, and 98° and 80. The patient was restless for some hours after readmission to the ward.

Fourth Operation.—Thirty-one days after the first operation diathermy of the left inferior turbinate and stump of the middle turbinate was performed under evipan anaesthesia with premedication. Omnopon 2/3 grain and scopolamine 1/150 grain were injected subcutaneously, one hour before the intravenous injection of sodium evipan. Nine c.c.m. of the standard solution of the latter was injected in one and a half minutes (4 c.c.m. in the first minute). The patient became comatose in forty-five seconds, and four minutes after the commencement of the injection, while diathermy was in progress, the patient began muttering but did not move. Diathermy was completed one minute later, and the patient was sent back to the ward asleep. Soon after being put back to bed she complained of feeling cold and breathless, and began twitching. She became cyanosed, and about fifty minutes after the evipan injection she stopped breathing. She was completely relaxed, had a ghastly colour, and at first sight appeared dead; but on examination the pulse was found to be regular but weak, and about 60 to the minute. Artificial

respiration was applied and oxygen administered. The colour improved rapidly, the patient was conscious, and talked within ten minutes of the commencement of the attack. One hour later she stopped breathing again. This time apnoea lasted five minutes, and the pulse rate dropped to 40 per minute. The same treatment was applied, and 1 c.cm. of icoral was injected subcutaneously. The patient was conscious again within ten minutes of the commencement of the attack. One and a half hours later there was a recurrence of the above symptoms lasting two minutes. For eight hours the patient complained of being unable to breathe naturally. The temperatures and pulse rates, as above, were respectively 98° and 80, 98.6° and 102, and 98.6° and 84. The blood pressure twenty-four hours after the operation was 104/70, and rose to 125/75 on the second day.

Discussion

The patient was not acutely ill at any time; her general condition was very good, and clinically the same for all four anaesthetics. The operative procedures varied in each instance, but, except for the first operation, were of a minor nature, and not sufficient to cause surgical shock of any degree. Some of the nausea and sickness following the first operation was undoubtedly due to the operation itself, and the anaesthetic was given for a longer period than for the other operations; but even with these reservations the post-anaesthetic discomfort seemed out of proportion when compared with that noticed in the case of the other anaesthetics. The patient also informed me that she had been "just as sick" following a short chloroform and ether anaesthetic for a submucous resection a year before. The temperatures and pulse rates given were taken in the morning and evening of the operation day, and the following evening. They show the least reaction with avertin, and the most with chloroform and ether, and evipan with premedication.

The surgeon has stated that, as far as he was concerned, all four anaesthetics were satisfactory. The anaesthetist found the simplest method was with chloroform and ether, and sodium evipan required but little preparation. Avertin had the disadvantage of requiring more time, as the solution had to be prepared about one hour before the operation.

The patient's point of view was summed up as follows.

- (1) *Chloroform and ether*: "Not so bad as people make out." "I don't like going under, but it doesn't last long." "It's the after-effects that are worse: I was sick all that day, and felt sick for days, and couldn't get rid of the smell."
- (2) *Evipan alone*: "I don't remember much except the needle prick and going off with a bump."
- (3) *Avertin, gas and oxygen*: "I just fell asleep and don't remember anything of what happened that day."
- (4) *Evipan with premedication*: "I thought it was the same as I had before, but that something went wrong." "I can remember something hurting terribly in my nose, and saying that it hurt, but I couldn't move. Then I don't remember anything till I was wheeled into the ward; I felt cold and couldn't breathe. I don't remember having any injections in bed." When asked which anaesthetic she would choose if she had to have another operation the patient replied, "The one I had in bed"—that is, avertin. When asked to give reasons, she replied: "It's the nicest going off, and upset me least afterwards." Evipan alone was given as second choice, and chloroform and ether was by far the worst.

The opinion of the nursing staff was that avertin caused more work and trouble than any of the other anaesthetics. The patient had to be watched carefully during the rectal injection, and was comatose for a prolonged period after the operation. Noises in the ward caused much restlessness, and she had to be under constant supervision. This has been noted in most hospital cases. In nursing homes and private wards a much quieter atmosphere can be maintained, and the patient has no period of restlessness.

Evipan with premedication was not successful in this case. This is rather surprising, in view of the fact that some days previously evipan alone had given an excellent result. I can give no explanation of this, but the case illustrates clearly the depressant action of evipan on the respiratory centre and also its selectivity for that centre. Three periods of apnoea occurred while the pulse remained good, except for a fall to 40 per minute for a short time. The case shows clearly that evipan is a "safe" anaesthetic in so far as, with normal doses, the cardiac centre seems to be very little affected.

Summary and Conclusions

1. A case has been described in which four different types of general anaesthetics were administered within a period of thirty-one days.
2. A description of the anaesthetics has been given.
3. The anaesthetics have been discussed from the patient's, the surgeon's, the anaesthetist's, and the nurse's point of view.
4. Avertin, with gas and oxygen, in this case, appears to be the most satisfactory form of anaesthetic, though the administration requires more time and attention.
5. Evipan alone proved very satisfactory in this case, and the selectivity of this drug for the respiratory centre is clearly illustrated.

In conclusion I would like to thank Mr. D. Ligat for his help and permission to publish this case. My thanks are also due to Dr. Grace and Dr. Hall for particulars of the first two anaesthetics.

Clinical Memoranda

COMPLETE CONGENITAL DIAPHRAGMATIC HERNIA IN AN ADULT: OPERATION

(With Special Plate)

The comparative infrequency of congenital diaphragmatic hernia in adult life renders this case of interest.

A healthy German girl, aged 20, who was on holiday in England, was recently admitted to the Farnborough Hospital as a case of acute pancreatitis. She had vomited once or twice, was somewhat collapsed, and had severe pain in the epigastrium. There was also severe pain in the region of the left shoulder. The temperature was 99.2° F., the pulse 120, and the respirations 26. The upper abdomen was slightly rigid. The heart sounds were heard on the right side, and breath sounds were deficient over the whole of the left lower chest. The diaphragmatic hernia was not suspected before operation, in spite of the dextrocardia.

On opening the abdomen there was a small quantity of free fluid which was slightly blood-stained, but the only viscera present were a collapsed descending colon, an enlarged and prolapsed liver, and the pelvic organs. The right Fallopian tube was lying in contact with the gall-bladder. High in the epigastrium could be felt the tense and distended lower end of the stomach. The emptiness of the peritoneal cavity and the complete absence of palpable and visible small gut led to a diagnosis of diaphragmatic hernia. The hand could be passed a little way into the chest along the greater curvature of the stomach, but owing to the enormous distension of this organ it was impossible to proceed further until the contents had been drained off. A stomach wash had not been given before the anaesthetic as there had been no symptoms of intestinal obstruction. After packing off the lower end of the stomach a catheter was inserted through a purse-string suture, and several pints of fluid were withdrawn. It was not possible to withdraw the stomach completely from the chest

Diagram showing condition found at operation

by means of gentle traction during each expiration; with it came the spleen, which was completely mobile. On passing the hand through the hernial orifice it was found that the left half of the diaphragm was almost completely absent. The chest contained all the small intestine, the omentum, and most of the large gut; it was possible to palpate the ribs almost up to the clavicle on this side. The intestines themselves did not appear to be distended, and in any case could not be mobilized. The patient's condition was very poor at this stage, and she was therefore returned to the ward, half a pint of warm saline being left in the peritoneal cavity.

She made fair progress for several days, and the bowels were well opened. There was a troublesome post-anaesthetic cough, and on the sixth day it appeared that the stomach passed back into the chest and again became obstructed. The patient vomited copiously, in spite of repeated aspiration of the stomach contents, and died on the seventh day after the operation.

An x-ray photograph taken in bed showed coils of small intestine occupying the upper half of the left chest. Unfortunately, permission for a post-mortem examination could not be obtained. It is interesting to note that the girl's parents stated that she had always been an ardent gymnast and had enjoyed perfect health throughout her life. She had complained occasionally of flatulence, and was unable to drink aerated waters.

Farnborough, Kent.

TREATMENT OF CLIMACTERIC HYPERPIESIA BY ARTIFICIAL MENOPAUSE

The following case, which is described in detail, may be of interest as suggestive of the hopeful prognosis which may be given if the treatment advocated is adopted in this particular type of high blood pressure.

In January, 1932, the patient, a married woman of 45, was suffering severely from symptoms of hyperpiesia, her usual systolic pressure being 220 mm. She had extensive retinal haemorrhages, and her condition was thought to be due to chronic nephritis, and was investigated thoroughly from this point of view; but the urine, blood urea, and urea concentration tests were found to be normal. The laevulose test was also normal, and showed no evidence of hepatic insufficiency. The Wassermann reaction was negative, the differential blood count was normal, and x rays showed no abnormality of the alimentary tract, nor was there any bacteriological evidence of intestinal or urinary infection. The teeth and antra were thoroughly examined and x-rayed, and found to be healthy, and there was no obvious sign or symptom of pelvic disease; the patient had had five children, of whom four were alive, and no miscarriages, and the periods occurred regularly every four weeks, being normal in amount and duration, with no sign of cessation, the patient's mother not having had a menopause until the age of 50. Her appearance suggested a slight hypothyroidism, and the basal metabolism was found to be -10 to -15 per cent. She was kept under observation for nine months, and it was found that her blood pressure rose and her symptoms were accentuated by each menstrual period, the occipital headache, which was a fairly constant symptom, becoming much worse at these times and a good deal of emotional disturbance occurring.

An artificial menopause suggested itself as a means of at least alleviating these severe exacerbations of the trouble, and this was carried out by means of radium in November, 1932, by Mr. Eardley Holland. She had two periods afterwards and has had none since. Her blood pressure gradually fell to 160-175 systolic, and has remained at that level without exception. The occipital headache has entirely disappeared, and the eye condition has improved to a surprising degree, there having been no fresh retinal haemorrhages in the last eighteen months. The whole condition of the patient has changed from invalidism to a life of ordinary activity.

In conclusion, I should like to thank Mr. Eardley Holland, who carried out the insertion of radium, for permission to publish these notes.

Huddersfield.

L. SHILLITO, M.B., B.Ch.

Reviews

THE MEDICAL ANNUAL

In their introduction to the *Medical Annual* for 1934¹ the editors, Dr. LETHEBY TIDY and Mr. RENDLE SHORT, remark that "an occasional grumble is heard that there is too much for the specialist and not enough for the general practitioner, particularly in the way of simple methods of treatment." They reply that this point has not been lost sight of, and that, although the *Medical Annual* is in the main a conspectus of current medical literature, special articles of practical value are included each year which are written independently of the literature. In our review of the 1933 volume, we suggested that this yearbook was remarkable in that it had something to offer to the student and to the general practitioner and to the specialist. In the new volume there are a "considerable number of therapeutic hints for the family doctor," but we think that those who have grumbled should not forget that both general practitioners and specialists are doctors who have received the same basic education. What is sauce for one should be sauce for the other, for if the general practitioner is not aware of what the various specialists are up to he will not know how and when he should avail himself of their special activities for the benefit of his patients.

There is, however, one problem which is of particular concern to the general practitioner—national health insurance practice—and we welcome in the present issue of the *Medical Annual* the excellent article on this subject by Dr. E. Kaye Le Fleming. In a clear and concise manner he explains how "the first big scheme of preventive medicine applied to general practice" is carried out by the 19,000 medical men engaged in this work in England and Wales and Scotland.

Where there is no chaff one cannot separate the wheat, but for convenience of review it may be permissible to distinguish between an abstract (specialist) wheat and a real (practical) wheat. Of the latter variety there is plenty, and, if the verbal somersault is allowed, such articles as those on cosmetics, stammering, vitamins, insomnia, anaemia, drunkenness, and anaesthesia—among many others—will make a ready appeal to the busy general practitioner who wants to lay his hands on something tangible. We should also like to draw attention to the extremely useful Practitioners' Index at the end of the book, where short descriptions of new drugs and medical and surgical appliances, lists of books, and details of special homes, institutions, spas, sanatoria, and medical societies can all readily be found with a flick of the thumb.

PROBLEMS OF LIFE AND MIND

Dr. C. G. JUNG's book on *Modern Man in Search of a Soul*² is a translation into English of a series of essays that have, in most instances, been delivered as lectures. Among the subjects discussed are dream analysis, the aims of psychotherapy, the stages of life, archaic man, the basic postulates of analytic psychology, and the spiritual problem of modern man—all these topics being approached from the standpoint of the analytic psychology of which Jung is the founder. With considerable courage the author ventures to suggest the possibility of

¹ *The Medical Annual: A Yearbook of Treatment and Practitioners' Index*. Edited by H. Letheby Tidy, M.A., M.D., F.R.C.P., and A. Rendle Short, M.D., B.Sc., F.R.C.S. Fifty-second year. Bistol: J. Wright and Sons, Ltd.; London: Simpkin Marshall, Ltd. 1934. (Pp. 644; illustrated. 2s. net.)

² *Modern Man in Search of a Soul*. By C. G. Jung. London: Kegan Paul, Trench, Trubner and Co. Ltd. 1933. (Pp. ix + 282. 10s. 6d. net.)

a "psychology with the psyche"—that is, a field of study based on the assumption of an autonomous psyche. He contends that since we have no idea of the way in which what is psychic can arise from physical elements, and yet cannot deny the reality of psychic events, we are free to frame our assumptions the other way about for once, and hold that the psyche arises from a spiritual principle which is inaccessible to matter. In practice, of course, all psychotherapists deal with their patients as if the mind—conscious and unconscious—were independent of the body, and it matters but little whether they accept or deny the existence of an independent entity or soul. The actual differences between the dynamic schools of psychopathology are to be found in therapeutic techniques and in the conceptions as to the nature and content of the unconscious. Jung's conception of the unconscious is certainly impressive. In addition to repressed material Jung recognizes a collective unconscious, this being the repository of primitive images or "archetypes of apprehension," which represent both the past stages of racial development and also the future potentialities. From this racial unconscious all creative possibilities and all the dynamic powers of the psyche are assumed to issue.

The technique of analytic therapy would seem to be difficult to explain, and it could obviously only be understood by those who have been themselves analysed. The results of treatment suggest a state of mind analogous to that occurring in religious conversion. The analysis is mainly concerned with the dreams of the patient, the aim being to convert the destructive powers of the unconscious into healing forces. The archetypes come to independent life and serve as spiritual guides for the personality, thus supplanting the inadequate ego with its futile willing and striving. When the patient has gained access to the hidden sources of psychic life it is found that this marks the beginning of the cure.

Dr. Jung reveals himself once more as an independent and original thinker and psychologist, and we can confidently recommend his book to those who are interested in the problems of life and mind. It certainly creates an impression that the educated classes in Switzerland who find difficulty in adjusting to the problems of life are seeking help more and more from the psychotherapists.

CLINICAL PHYSIOLOGY OF THE EYE

In a recent discussion between some budding doctors, one of them, a man with a brilliant academic career, said that as far as eye work was concerned that had become so scientific as to have lost the zest of search; certainty and stability had destroyed the romance of the unknown. If anyone should seriously be of this mind he might well study a book entitled *Clinical Studies on the Physiology of the Eye*,³ by J. GRANDSON BYRNE. In this work there is collected a series of observations on the eye which are full of interest, and calculated to arouse in the most complacent of methodical clinicians a new spirit of inquiry and perhaps of vehement opposition. The author first considers the relation of the critical and affective nervous systems, then the effector mechanisms which mediate palpebral, pupillary, and lens movements. Next follow observations on the paradoxical pupillary dilatation and constriction associated with somatic lesions and the mechanism of accommodation, and on visceral disorders associated with referred pain and hyperalgesia. There are other chapters, but these form the main contents.

There is no medical practitioner who does not know the phenomenon of the Argyll Robertson pupil and its

significance, and also something of the nervous mechanism of its production. That reaction is an exemplar of many others, and it is with these that Dr. Byrne's book is particularly concerned. He enters into a fuller explanation of the Argyll Robertson phenomenon, and propounds other rarer and less certain pupillary reactions set up by local and general bodily disorders. For some of these he makes out a good case; others—for example, "pupil inequality and ulcer of the leg"—seem somewhat too subtle and leave room for doubt, yet there is enough apparent evidence to warrant further investigation. The author draws a most practical moral from his observations in these words:

"From the foregoing it is apparent that the practice of ophthalmology, like that of any other specialty, should be undertaken only by one who has had a thorough training in the theory and practice of medicine, followed by a long period (*plurimos annos*) of general practice. The determination of the patient's refraction and the prescribing of glasses may seem to be an easy matter, but—from the standpoint of the patient's welfare in general, not to mention the early, complete, and speedy recovery of ocular function—it is by no means an easy matter, and should not be so regarded by anyone who assumes the responsibility of treating disordered ocular function."

THE DEVELOPMENT OF RADIOLOGY

The Science of Radiology,⁴ edited by OTTO GLASSER, is a charming book of infinite variety. In 1929 steps were taken to organize a congress of radiology in connexion with the project for holding an international exposition in Chicago, which would deal with the progress of science during the past 100 years. In 1931 the four national radiological organizations of North America decided to co-operate in the organization of the first American Congress of Radiology. Dr. Byron H. Jackson of Scranton, Pennsylvania, was appointed chairman of the committee on history and education. One of the duties of this committee was the editing of a book that would denote the outstanding features developed in the science of radiology from the time of Roentgen's discovery up to the period of the congress. Dr. Otto Glasser was appointed editor, and with the assistance of twenty-five contributors, each of whom is an authority on the special branch of the subject on which he writes, he has produced a book of a character unique in the history of radiology. Although the volume deals mainly with the development of radiology in the United States, the book has an international appeal, for the authors have drawn upon the radiological literature of all countries.

In the opening chapter Dr. Glasser, who is the author of the standard work on the life of Roentgen, describes the discovery of the Roentgen rays, and gives a very brief account of Roentgen's life, effectively disposing of the myths and fables which became associated with the great discovery. Then follows a short account of the discovery of radium by Pierre and Marie Curie, due credit being given to Henri Poincaré, the French scientist, who a few weeks after Roentgen's discovery suggested the investigation of fluorescent substances, and to Henri Becquerel, who undertook their systematic study. Becquerel's experiments with uranium salts and their action on photographic plates led to the discovery that penetrating and invisible rays were emitted from all uranium compounds, whether these were fluorescent or not. His work showed that these rays were similar to the x rays, and that they were a special property of the atom itself; in fact, an entirely new property of matter had been discovered. The story is then told of Pierre and Marie Curie's research work on the Becquerel radiation, and, finally, of their discovery of radium. On these

³ *Clinical Studies on the Physiology of the Eye* By J. Grandson Byrne, M.A., M.D. London, H. K. Lewis and Co., Ltd. 1934. (Pp. 144; 39 figures. 10s. 6d. net.)

⁴ *The Science of Radiology*. Edited by Otto Glasser, Ph.D. London: Baillière, Tindall and Cox. 1933. (Pp. xiv + 450; 168 figures. 25s.)

foundations the whole science of radiology has been erected.

In subsequent chapters every branch of radiology is dealt with by well-known American specialists. One chapter is devoted to the American pioneers in radiology, and is of great historical interest. X-ray physics, x-ray apparatus, and radiological diagnosis and treatment are all chapters of absorbing interest, and an excellent account is included of x-ray cinematography, due credit being given to Macintyre of Glasgow, who in the first volume of the *Archives of Skiagraphy* (April, 1897) published a paper on x-ray cinematography. He had previously, at a meeting of the Glasgow Philosophical Society, shown an x-ray cinematographic film of the movements of the leg of a frog, and it is interesting to remember that Macintyre described both the direct and the indirect methods of x-ray cinematography. Military roentgenology is an interesting chapter, and a fascinating story is told of the use of x rays in warfare.

The reader will find that in this book the history of radiology in all its branches is accurately given; and even the most recent developments in radiology, such as the nature of the cosmic rays and the Gurwitsch rays, find a place. Numerous references are given. The illustrations are of excellent quality, and a good index is provided. It is with confidence that we recommend this book to radiologists both young and old.

SYNOPSIS OF HYGIENE

The fourth edition of the well-known *Synopsis of Hygiene*,⁵ by Professor JAMESON and Lieut.-Colonel PARKINSON, follows the third at an interval of less than four years. It amply sustains the merits of its predecessor, and adds new virtues besides. The work contains much fresh material, for which room is made without increase of bulk by the omission of the purely laboratory section on chemical methods. The order of subjects, which has been recast, gives priority to the more social topics. The opening section is concerned with health authorities and their powers, sanitary officers and their duties, and health propaganda. The specific fevers are next dealt with in turn, all information supplied being well up to date. Then follow articles on industrial disease, the animal parasites, and hospitals.

The section on the welfare services, which has been most usefully enlarged, includes the findings of the Maternal Mortality and Morbidity Committee, discusses the question of a national maternity service, and supplies detail enough, without over-elaboration, on maternity and child welfare schemes to convey a clear impression of the scope and character of the work. Under "schools" the problems of the mentally and the physically defective child are well presented. "Personal Hygiene," an excellent article, passes on to nutrition, family budgets, and the open-air life. Among other subjects treated are food, ventilation, and water supplies, the last including new methods of purification, such as catadyn sand. The essentials of sewage disposal and housing are set forth in an interesting way. The substantial section on sanitary law appears to omit no points of importance. Meteorology figures in an appendix along with a table of food values and a summary of physical and chemical factors.

The book makes ample provision for the needs of the student, and by means of its numerous references points the way to further progress. In 1930 we recommended the third edition to those preparing themselves for the Diploma in Public Health. We repeat that recommendation now in the case of the fourth with added cordiality.

⁵ *Synopsis of Hygiene*. By W. Wilson Jameson, M.D., F.R.C.P., D.P.H., Bacteriologist, and G. S. Parkinson, D.S.O., M.R.C.P., D.P.H., Lieut.-Colonel R.A.M.C. (ret.). Fourth Edition. London: J. and A. Churchill, Ltd. 1934. (Pp. 619; 17 plates, 214).

THE NEWBORN

Dr. ERIC PRITCHARD has collected into book form the lectures on the care of newborn babies given during the past few years to students at Queen Charlotte's Hospital, and although the title-page of *The New-Born Baby*⁶ states that it is a manual for midwives and maternity nurses, it should also prove useful for medical students and practitioners. There is a paucity of easily available information on this important age period, for, divided between textbooks on midwifery and on paediatrics, diseases of the newborn suffer from a sort of scattered responsibility. Such subjects as the premature infant, ophthalmia neonatorum, infections in the newborn, and the skin of the newborn are especially well described, while there is an excellent section on nursery fallacies, which exposes the foolishness of dummies, lime-water, lullabies, and domestic measures. On the artificial feeding of the newborn, however, this little book appears rather too complicated for the average maternity nurse. How the midwife, attending mothers in their homes, is to undertake the modification of cow's milk suggested, including the making of whey and a subsequent peptonization for three hours, is not explained. Some easier procedure should be advocated and explained. Nor does the section on constipation seem the wisest sort of teaching for the nursing profession, with six drugs described as of value in the course of the first page and training mentioned only on the second. The style throughout is clear and the teaching dogmatic, with many happy illustrations. Candidates for the C.M.B. should find the book of value, especially if the examiners could also be persuaded to read it.

Notes on Books

The second edition of Professor BECKMAN's *Treatment in General Practice*⁷ is a book for the use of medical practitioners. Every disease is given its separate heading, and the appropriate treatments, diets, and drugs are considered in detail. The volume contains a great deal of information, and is brightly and breezily written in a style that will no doubt find many admirers. It may be taken to represent current American practice, is furnished with a bibliography and an index, and can be cordially recommended to the readers for whom it is designed.

The volume of selected *Researches Published from the Wards and Laboratories of the London Hospital during 1933*⁸ contains over thirty reprints of papers published in various medical, pathological, or physiological periodicals during the year. Most of them come from the wards, and their perusal gives the reader a clear impression of the skill and keenness with which the workers in that great institution make use of the opportunities for research with which they find themselves surrounded.

Dr. B. DE RUDDER's work on *The Acute Infectious Diseases of Civilization*⁹ contains, as its subtitle indicates, a discussion on the epidemiology and control of the commonest infectious diseases—such as measles, small-pox, whooping-cough, scarlet fever, diphtheria, and poliomyelitis. The work is divided into two parts. In the first the author discusses in turn the epidemiology and endemiology of the diseases named, the doctrine of latent and spontaneous immunization, the influence of seasons and climate on infectious diseases, and their incidence and mortality in various countries; while in the second he deals

⁶ *The New-Born Baby. A Manual for the Use of Midwives and Maternity Nurses*. London: H. Kimpton. 1934. (Pp. 272; 8 figures. 4s. 6d. net.)

⁷ *Treatment in General Practice*. By Professor H. Beckman, M.D. Second edition. Philadelphia and London: W. B. Saunders Company. (Pp. 889; 45s. net.)

⁸ *The London Hospital Researches*. By Dr. B. de Rudder. Leipzig: Georg Thieme. 1934. (Pp. 286; 49 figures. M.16; bound, M.18.)

⁹ *The Acute Infectious Diseases of Civilization*. By Dr. B. de Rudder. Leipzig: Georg Thieme. 1934. (7s. 6d. net.)

with notification and isolation, disinfection, return cases, the carrier problem, the serum prophylaxis of measles, whooping-cough and poliomyelitis, and active and passive immunization against diphtheria and scarlet fever. An appendix of mainly German and American literature is included.

The thirteenth issue of "The Year's Practical Medicine" ¹⁰ has been issued under the continuing editorship of Dr. CAMILLE LIAN, and contains an index for the last five years. The barbiturate controversy seems to have arisen in France, for three contributors deal with certain aspects of these drugs. The x-ray appearances in pneumoconiosis are well reviewed, and the up-to-date nature of the production is illustrated by a good description of the basophil syndrome of pituitary dysfunction, and another of the Schuller-Christian syndrome. There is, however, still too much neglect of work done outside France.

There is no substitute for skilled personal instruction in the difficult task of teaching a sufferer from cleft palate to speak properly with what Nature, the surgeon, and the mechanic have between them given him for that purpose. But to those who cannot get the aid of a specialist in this teaching no better guide could be found than the monograph *Cleft Palate Speech*, ¹¹ in which Miss VAN THAL gives detailed advice as to the necessary training of both mind and body.

¹⁰ *L'Année Médicale Pratique*. Edited by Dr. Camille Lian. Thirteenth year. Paris: René Lépine. 1934. (Pp. 662; 6 figures. 26 fr.)

¹¹ London: Allen and Unwin, Ltd. 1934. (Pp. 94; illustrated. 3s. net.)

Preparations and Appliances

PYELO-LITHOTOMY FORCEPS

Mr. W. K. IRWIN, F.R.C.S. (London, W.), writes:

When removing calculi through an incision in the renal pelvis I had often found difficulty in manipulating the ordinary type of forceps, especially if the patient was stout, the pedicle short, and the kidney not readily mobilizable. I therefore designed a special instrument, which has been much used during the past six years. A new pattern, which is a material improvement, has now been made in accordance with my suggestions.

In the new model, shown in the accompanying illustration, the inner end, for grasping the calculus, is $1\frac{1}{2}$ inches long, is bent at a right angle to the handle, and has concave fenestrated jaws. The handle portion is $4\frac{1}{2}$ inches in length. The whole instrument is stronger than in the first pattern. With such a forceps one can work in a much more limited space than with a straight or nearly straight type.

The instrument is obtainable from Messrs. Down Bros., St. Thomas's Street, S.E.1.

AN IMPROVED CLINICAL THERMOMETER CASE

Dr. B. RICHARDSON BILLINGS (Folkestone) writes:

Appalled at the "mortality" of clinical thermometers under average conditions, I have designed a case which protects a thermometer during the vulnerable periods of its career. Until clinical thermometers can be made so as to be absolutely indestructible, we must put up with breakage due to accidental dropping, though quite a number are broken in the thin case usually provided as a container. Moreover, these cases do not sterilize the thermometer.

The container I have devised is a strong metal tube longitudinally fenestrated, and lined with a pyrex glass tube (the strongest glass known), the ends of this lining being ground to a watertight fit against washers at each end. The lower end of this tube has a light compression spring-loaded ferrule, in which the bulb of the thermometer is held. The screw-cap at the other end presses the thermometer down into the tube and keeps it comfortably housed, in spirit or other antiseptic; a clip, of the fountain pen type, keeps the case snug in one's

pocket. Thus the thermometer is kept safe, sterile, and ready to hand. Risk of damage through undue pressure being applied (as, for instance, when leaned upon while in the waistcoat pocket) is minimized. In the rare contingency of the glass liner becoming damaged, this can easily be replaced at a cost far below that of a new thermometer. Owing to atmospheric

pressure, when the thermometer has been extracted and the case laid on its side, the fluid does not run out.

The Holborn Surgical Instrument Co., Ltd., 26, Thavies Inn, E.C.1, have ably carried out my design, and are prepared to sell these containers at five shillings each, spare barrels being sixpence.

TESTING PATENCY OF FALLOPIAN TUBES

Mr. F. NEON REYNOLDS, F.R.C.S. (London, W.), writes:

The apparatus shown is for the investigation of the patency of the Fallopian tubes.

The illustration needs no lengthy explanation. A is a CO₂ sparklet bulb; B, a needle valve control; C, a manometer; D, the connexion for rubber tubing leading to the uterine

cannula; and E is a relief valve, which can be set to "go off" at any desired pressure. This relief valve is a safeguard in that it prevents the pressure rising to a dangerous degree should the supply valve be opened too fully and suddenly by any inexperienced assistant.

The main advantage of the apparatus, however, and the one for which it was designed, lies in its size. It measures $8\frac{1}{2}$ by $3\frac{1}{2}$ by 3 inches, and can be carried easily in one's ordinary instrument bag. Those who prefer to use CO₂ instead of air can thus be relieved of carrying an extra and somewhat bulky addition to their ordinary impedimenta.

The apparatus is made by Messrs. A. Charles King, Ltd., 34, Devonshire Street, W.1.

A RADON SEED INTRODUCER

Dr. SYLVIA B. WIGDER (National Radium Centre, Bristol Royal Infirmary) writes:

The accompanying illustration shows an instrument I designed some little while ago. Experience has proved it of great assistance, and I should like to mention some of its advantages.

The instrument is quite simple in construction. It is loaded at the point, a slit carrying the silk to prevent cutting, while a little vaseline makes it possible to use all sizes of seeds.

One hand only is required to use the instrument, the other being free to steady the growth. The curve has made the introducer adaptable for almost any situation. By having the silks of equal lengths it is, of course, easy to determine the depths the seeds are inserted by the portion remaining above the growth.

I have to thank Messrs. Allen and Hanburys for the manufacture of the instrument, and for the great care they have taken in following my instructions.

British Medical Journal

SATURDAY, JUNE 9th, 1934

TUBERCULOSIS AND THE MILK SUPPLY

On November 2nd, 1932, the Prime Minister appointed a committee of the Economic Advisory Council with the following terms of reference: "To consider what practical measures can be taken to secure a reduction of disease among milk cattle in this country, and to report upon any changes desirable in the existing administrative practice, and, in particular, upon the value and practicability of methods for reducing the incidence of bovine tuberculosis and improving the milk supply." The Committee, with Sir Frederick Gowland Hopkins in the chair, after receiving evidence from numerous sources, has at last published its eagerly awaited report.¹ Though the report itself contains a wealth of information on the frequency of disease in cattle and of milk-borne disease in man, on the nutritive value of milk, and on the effect of pasteurization on the individual constituents of milk, as well as a critical summary of existing legislation, it is on its proposed recommendations for improving the present position that interest must be chiefly centred. Before considering these in detail, it must be pointed out that the Committee has restricted itself almost entirely to bovine tuberculosis and its effect on the milk supply. It has left, at any rate temporarily, the problem of eradicating contagious abortion, mastitis, and Johne's disease to the initiative of the farmer, and it has not squarely faced the problem of milk-borne disease, which would still exist even if tuberculosis was eradicated.

The three main lines of recommended administrative development may be summarized as follows: (1) An extension of routine veterinary inspection. It is proposed that veterinary inspection should be made obligatory on all local authorities, and that a veterinary service should be built up consisting largely of whole-time officers with a training in veterinary State medicine. (2) An active policy for the eradication of bovine tuberculosis. It is realized that the Tuberculosis Order, 1925, has done nothing to reduce the incidence of tuberculosis in cattle, and that the only sound method for combating this disease is the building up of tuberculosis-free herds. To achieve this end a scheme is outlined, and various inducements are held out to owners to secure their co-operation in it. A list of tuberculosis-free herds (accepted herds) is to be instituted, together with a list of herds whose owners are making bona fide efforts under official control to free them of tuberculosis (supervised herds). Free veterinary advice and free tuberculin testing are to be provided, financial help where necessary is to be forthcoming, and a higher price is to be paid for milk from tuberculosis-free

herds by means of a levy on other types of milk. (3) Regulations governing the grading of milk and the granting to large urban authorities of the right to require pasteurization of milk other than that produced by herds free from tuberculosis.

The third recommendation involves far-reaching proposals. In the first place it is maintained that all liquid milk for human consumption should be sold under an official designation, and that all such milk, whether to be consumed in the raw or pasteurized state, must attain a certain standard of cleanliness on the farm. Four grades of milk are suggested: (a) *certified milk*, derived from tuberculosis-free herds, to be sold raw, with no necessity, as at present, for bottling to be performed on the farm; (b) *pasteurized milk*—namely, milk which has been heated once in a licensed plant by a process approved by the Ministry of Health or the Department of Health for Scotland; (c) *sterilized milk*—namely, milk which has been raised to the boiling point or higher in a plant licensed for the purpose; (d) *milk (uncertified)*—namely, milk which has undergone no form of heat treatment, which is not derived from tuberculosis-free herds, but which attains a certain hygienic standard. In the second place it is laid down that the council of any county borough, municipal borough, large burgh, or urban district in an area the population of which exceeds 100,000, and the London County Council, shall have the right to prohibit the sale of milk (uncertified) within five years of initiation of the tuberculosis eradication scheme, provided it has given not less than two years' notice of its intention to do so.

These recommendations are framed in an endeavour to achieve the maximum gain in public health with the infliction of the least hardship on the producer-retailers in the large towns. It is contended that the immediate institution of compulsory pasteurization in large towns would deprive a large number of farmers, who produce and sell their own milk on the outskirts, of their present means of livelihood. The proposal, therefore, is to offer these producer-retailers the alternative of pasteurizing their milk or of freeing their herds from tuberculosis within five years. So far as small towns and country districts are concerned, where compulsory pasteurization is at present impracticable, reliance is to be placed on increasing the supply of milk from tuberculosis-free herds and on educating the public to boil all milk which is not of certified standard. If the recommendations in this report are fully implemented, they will undoubtedly go some way towards safeguarding the public health—at any rate in the large towns. Whether they will be successful in leading to a reduction of tuberculosis in cattle is another question. In the long run an adequate economic stimulus for building up tuberculosis-free herds must depend on a demand for milk from this type of herd. But where is this demand to come from? It is known that raw milk from tuberculin-tested herds is not free from the risk of carrying other diseases, and it is difficult to imagine how any medical

¹ Cmd. 1591. Economic Advisory Council Committee on Cattle Diseases Report, May, 1934. H.M. Stationery Office. (2s. 6d. net.)

adviser, aware of this fact, is going to recommend—in large towns, where a choice is available, the consumption of raw potentially dangerous certified milk at a higher price in preference to pasteurized safe milk of Grade A standard at a lower price. The objection felt by some people at present to pasteurized milk—namely, that, even though safe, it is often produced under uncleanly conditions and is aesthetically undesirable—will no longer hold good, because a pre-pasteurization standard of cleanliness is to be enforced.

It is, however, premature to discuss the possible outcome of this report until it is known how far the Government proposes to adopt the Committee's recommendations. That it calls for a substantial advance in public health legislation is very gratifying, and that it represents a determined effort to improve the cleanliness and safety of the milk supply is a matter for especial congratulation. While we cannot go all the way with the distinguished botanist "F. K.," who writes on this subject so eloquently in *Nature* of June 2nd, we echo his plea that "a great national effort must be made to discover means of securing to the people, all the year round, plentiful supplies of the best milk that Nature and art can produce."

THE BRITISH HEALTH INSURANCE SYSTEM

Some incorrect impressions of British national health insurance have found their way across the Atlantic, and to put the matter in a truer perspective for American readers Sir Henry Brackenbury has contributed an article to the *New England Journal of Medicine*. He finds no difficulty in proving that on the results of twenty-one years' administration there has been marked benefit both to the insured community and to the medical profession working under the Acts. He points to the resolution which the Representative Body of the British Medical Association passed eight years ago, almost without dissent, affirming that the measure of success attending the experiment had been sufficient to justify the profession in uniting to secure its continuance and improvement, and also to the memorandum of evidence presented by the British Medical Association to the Royal Commission, in which eight specific advantages are enumerated.

No one can say to what extent the national health insurance system has been responsible for the marked improvement in national health during the last two decades, notwithstanding war and economic calamities. The effects of insurance cannot be separated from other agencies, such as an increase in the knowledge of medicine and ancillary sciences, more effective public health administration, and popular education in hygiene; but the beneficial result of all these agencies must have been largely augmented by the activities of the insurance practitioner. To the medical profession itself national health insurance has brought advantages. Practitioners are learning to be colleagues rather than

rivals; family practice and the various branches of the public health service are being brought into better relationship. Many practitioners have found it a relief to be able to give a fuller attention to their poorer patients without the feeling that they will be distressed afterwards by the presentation of a bill. Large numbers of general practitioners in poor areas would have found it difficult to-day, without the insurance system, to earn by the exercise of their profession sufficient income on which to live. Sir Henry Brackenbury is careful to add that the money coming to them through these arrangements has been fully earned; it is the greatly increased amount of work which has led to this financial improvement, and notwithstanding the increase in quantity of service, there is no evidence of any deterioration in quality.

Certain drawbacks undoubtedly there are. The multiplicity of rules and regulations is often mentioned, but this arises from three valuable features in the system: the right of every member of the medical profession to enter the service; the close approximation of its conditions to those obtaining in private practice; and the considerable share assigned to the profession itself in the administration. The very confidence shown in the profession which these features disclose necessitates provision to deal with occasional negligence or delinquency and to safeguard the service from any untoward consequences of this freedom. Sir Henry Brackenbury admits that there is a tendency to multiply and complicate rules unnecessarily, but in general it may be said that they do not trouble the practitioner much more than the ordinary requirements of the penal code trouble the law-abiding citizen. Two other points of some importance are mentioned. The more easily transferable character of insurance practice facilitates the procedures of commercially minded practitioners and the exploitation of the profession by ingenious laymen. Again, with a small proportion of insured persons there is a tendency to demand the doctor's services as a business right and to be critical and suspicious lest they should not secure their full due. But the majority of insured persons enter into relations with their practitioners in the right spirit.

If as a result of British experience advice were offered elsewhere Sir Henry Brackenbury would lay it down, first of all, that the three unusual features of the British scheme already mentioned should be regarded as fundamental—namely, (1) the right of all doctors to be members of the service, (2) the absence of interference between doctor and patient as such, and (3) the appropriate association of the profession with the administration of the scheme. To these he would add three others, which will not be unfamiliar to readers of the *British Medical Journal*: that medical advice and treatment must be separated as completely as possible from any insurance provision for cash payments; that the scheme from the beginning should make provision not only for a general practitioner service, but also for consultant, specialist, and other ancillary services, and if possible institutional treatment; and that the administration

should be as simple as possible, in topographical areas, and not through a multiplicity of approved societies. In Great Britain, owing to interests already established, it has been recognized that approved societies may need to be represented on whatever local committees administer the scheme. In the Proposals for a General Medical Service for the Nation, issued by the British Medical Association in 1930, an extension of the scheme to dependants is urged, also the inclusion of specialist service and hospital care. Financial stringency has prevented any attempt to establish such provision during the past three years, but the scheme has been very favourably received, and if Sir Henry Brackenbury had written a little later he would no doubt have added that a conference of bodies interested in the subject is projected for the not distant future.

WORK OF THE G.M.C.

The General Medical Council completed the business of its summer session in five days, but only by putting in several hours of "overtime." Its work consisted almost entirely of the consideration of charges against practitioners, but although fourteen medical men came before the Council on charges of varying gravity, only three erasures were made. Of the three, two followed convictions for serious offences, and the third followed upon the proof of professional relationship between the respondent and co-respondent in divorce proceedings. In three cases in which there had been convictions for drunkenness or cognate offences the facts were found proved, but judgement was suspended until a later session. In one of these in which the practitioner had on a previous occasion been before the Council following a similar offence, and had broken the promise he then gave, the Council took the unusual course of postponing judgement for as long as two years, and required the practitioner to report at the end of the first year. Two cases of alleged canvassing were investigated, and one of them dismissed. In the other, certain facts were found proved, and judgement was postponed. These cases are the most tedious which the Council has to try, for they are usually brought by other doctors in the neighbourhood, whose evidence must be closely tested, and the story has to be pieced together from a number of witnesses the value of whose individual testimony may only be slight. A case which aroused comment in the Press concerned a neurological physician of high repute who had given an interview to a responsible Sunday newspaper, stating his view that barbitone compounds were most valuable and satisfactory hypnotics, and that so far as any addiction was concerned this did not develop out of their medical administration but nearly always arose from repeated personal attempts to counteract depression and insomnia. There are many experienced members of the profession who share this opinion and welcome its public ventilation by a well-known teacher. Exception was taken to a laudatory description of the specialist by the journalist. The Council thought the article "unwise," but accepted Dr. Collier's assurance that his motive was not, as alleged in the charge, to promote his own professional advantage. Here the complainant was a layman with a grievance; and if

the Council had declined to consider the case at all we should no doubt have heard it said in some quarters: "The G.M.C. has one law for the poor G.P. and another for Wimpole Street." Another case arose out of a complaint against an insurance practitioner, and was reported to the Council by the Minister of Health, who, however, was not represented at the inquiry. This practitioner, so the allegation ran, had falsely represented to his insurance committee that he had been paid certain sums by four insured patients for special treatment, which he thought, wrongly, to be outside the terms of service, whereas in fact he had received from them larger sums (in one of the cases much larger). The medical services subcommittee had found that the doctor afforded certain services and received fees therefor in addition to those notified by him to the committee, and failed to notify such additional services and fees. He was severely censured by the insurance committee; representations were made for a deduction from his remuneration—actually £15 was deducted—and he was ordered to refund the amounts he had charged, but no recommendation was made for the removal of his name from the list, though the Ministry reported the case to the General Medical Council, to whom the only penalty open is the larger one of erasure from the *Medical Register*. The evidence brought before the Council, however, came down to the evidence of only one of the four patients, who himself was too ill to give very clear testimony. On the other hand, the practitioner was able to bring forward evidence—that of his dispenser—which, through a misunderstanding, was not given at the medical services subcommittee hearing, and which bore out his own statement that these additional payments were not in fact received by him. He had not appealed, believing that the monetary penalty finished the case. The Council found the facts not proved, and the case was dismissed. The Council took the unusual course of reversing the findings of the Dental Board in two cases in which the Board had recommended that dentists should be struck off for alleged contraventions of professional ethics, in one case for circularizing former patients of the practice, and in the other for instituting a clinic for poor persons and inducing local medical practitioners to make the clinic known. It is rare—though it has happened at least once before—for the Council to upset the finding of the Dental Board. The Council, like the court of appeal in criminal cases, does not rehear the evidence, but has to accept the facts as found by the Dental Board.

THE BIRTHDAY HONOURS

The list of medical honours announced on the occasion of His Majesty's sixty-ninth birthday will be found at page 1042. Sir Milsom Rees, who has held the appointment of laryngologist to Their Majesties since the King's accession in 1910, is promoted to be G.C.V.O. Dr. Ambrose Thomas Stanton, who for the past eight years has been chief medical adviser to the Secretary of State for the Colonies, is promoted to be K.C.M.G. Dr. Maurice Alan Cassidy, physician-extraordinary to the King and senior physician to St. Thomas's Hospital, is created K.C.V.O. Dr. Frederick Grant Banting, Nobel prizeman, was appointed in 1923 professor of medical research at the University of Toronto in recogni-

tion of his large part in the discovery of insulin, and now becomes K.B.E. The honour of knight bachelor is to be conferred on five members of the medical profession. Major Robert George Archibald, R.A.M.C. (ret.), has been director of the Wellcome Tropical Research Laboratories at Khartum since 1920. Mr. Comyns Berkeley, consulting obstetric and gynaecological surgeon to the Middlesex Hospital, is vice-chairman of the National Radium Commission, and director of the L.C.C. Radium Centre at Hampstead. Professor Grafton Elliot Smith, F.R.S., famous in the world of anthropology and Egyptology, has for many years held the chair of anatomy at University College in the University of London. Major-General James Drummond Graham lately relinquished the post of public health commissioner with the Government of India, and was for a time officiating Director-General of the Indian Medical Service. Rai Bahadur Upendra Nath Brahmachari is a well-known civilian practitioner in Bengal. Our readers generally will welcome these rewards for distinguished service in varied fields of medical practice, research, and administration, while members of the Metropolitan Counties Branch of the British Medical Association, of which he has been treasurer and president, will note with particular pleasure the honour bestowed on Mr. Comyns Berkeley. In the list of those upon whom a knighthood is to be conferred there appear also the names of two men having close links with medicine: Captain Ian Fraser, M.P., chairman of St. Dunstan's, whose services on behalf of the blind are appreciated far and wide; and Mr. Samuel Brighouse, for many years coroner for South-West Lancashire, and still active at the age of 84. Miss Lloyd Still, matron of St. Thomas's Hospital, receives the honour of D.B.E. during her presidency of the International Council of Nurses.

TREATMENT OF SPRAIN

Just four years ago Leriche drew attention to the rich sensory innervation of the articular ligaments, and later he came to the conclusion that irritation of these nerve endings is an important factor in the disability that so often follows the common sprain. In his opinion the actual lesion in this condition is not a gross rupture of the ligaments or capsule, but rather a molecular disturbance of the white fibrous tissue. This led to vasomotor disturbances, oedema, and irritation of the sensory nerve endings. These findings led Leriche and Fontaine to try the effect of intraligamentous injections of novocain in cases of sprain, and they found that pain and limitation of movement, in fact all disability, disappeared immediately after the first injection, though in some cases in which symptoms recurred it was found necessary to repeat the injections on the second and third days. Two recent communications from other observers contain reports of cases similarly treated and with equally favourable results.¹ Although it may be true that macroscopic lesions—tearing of fibrous tissue and extravasation of blood—are absent in some very mild joint injuries, it must be borne in mind that "sprain" is a clinical term that covers almost all the minor injuries of joints short of gross ligamentous rupture, subluxation, dislocation, and fracture. The

whole group of injuries forms a continuous crescendo rather than a series of disconnected conditions. From the practical point of view, therefore, Leriche's conception of sprain is of doubtful value, seeing that there is no way of distinguishing clinically between his mild cases of "molecular" sprain and those common injuries in which partial rupture of ligaments and haemorrhage undoubtedly take place. Localized tenderness and swelling are present in both. Practitioners in this country have been brought up to believe that rest to the damaged part, followed by graduated exercise, is as necessary in the treatment of sprain as in any other type of injury, and there is no doubt that the Hiltonian treatment properly applied is very effective in most cases. Apparently, however, Leriche and his followers prefer the intraligamentous injection of novocain. The injection must certainly relieve the pain; yet it is difficult to suppose that it has any beneficial action on the injured ligament. Nevertheless, the results reported are most striking, particularly in cases of trauma to the shoulder, where rest followed by graduated exercise too often fails to alleviate the pain and stiffness that are such a troublesome feature in this particular injury. Though the rationale of Leriche's method of treatment may be obscure, it merits wide clinical trial. It is simple and apparently effective.

SUDDEN DEATHS OF SWIMMERS

There are few deaths so mysteriously tragic as that of the apparently robust and practised swimmer who suddenly sinks like a stone. Dr. A. Ravina and Dr. Simone Lyon¹ have lately tried to disentangle the conflicting theories advanced from time to time to explain this manner of death, and they devote particular attention to the work of Dr. Verhoogen.² His explanation assumes the existence of anaphylactic sensitiveness to thermal impressions. It may be congenital and hereditary, but generally it is acquired. The anaphylactic shock caused by cold water induces rapid vasomotor paralysis and general muscular impotence. Verhoogen records the case of a man who nearly died while bathing in a mountain lake, and who for several years had been subject to attacks of urticaria, shivering, and general debility when his skin came into contact with cold water. In Verhoogen's opinion this condition is by no means rare, and he recognizes it in those cases of pruritus and urticaria for which bathers commonly give jelly-fish the blame. According to another school, associated with the name of de Gurbert, the sudden collapse of the swimmer is due to an upset of his digestive mechanism, and occurs during the first two or three hours after a meal, when the food is still so inadequately digested that, under the influence of cold, it acts as a foreign protein whose sudden absorption by the circulation has disastrous effects—anaphylactic shock, of a kind. On this view, the risk of sudden death is less immediately after a meal, when the food is still insufficiently digested to be absorbed too quickly. According to a third theory, that of Frommel, most of these sudden deaths are the result of the sudden action of cold water on the nasal mucosa. The nasal branch of the trigeminal nerve is supposed to be responsible for a triple reflex provoking respiratory

inhibition with transitory arrest of the movements of the lungs, cardiac inhibition with bradycardia, and a rise of the systolic with a fall of the diastolic blood pressure. The trigeminal may also be held responsible for those cases in which a "header" from a good height brings one ear in painful contact with the water, or the swimmer goes to such a depth that pressure on the tympanum becomes great. The theory attaching special importance to disturbances of the semicircular canals may explain the inability to co-ordinate his movements from which the bather suddenly suffers, but not his complete collapse. Dr. Ravina and Dr. Lyon find that Verhoogen's theory has the merit of offering prophylactic and therapeutic remedies. If it should prove correct, and if all bathers were medically examined, the potential victims of these drowning accidents could be detected and advised not to venture into cold water. For a lump of ice or a compress soaked in ether applied to the forearm for a couple of minutes would, it is suggested, raise a papular rash in a quarter of an hour, betraying this form of idiosyncrasy.

THE "ACH" INDEX OF NUTRITION

The search for some method of picking out undernourished children from big groups by a simple test or tests continues, and the latest index to be suggested has the backing of the American Child Health Association. In a new pamphlet¹ by Drs. Raymond Franzen and George T. Palmer, and in an article² by the former author, the details and value of the "ACH index" are set out and discussed. The letters stand for "arm," "chest," and "hip," and the aim of the index is the aim of other indices—namely, to identify children with small amounts of musculature and subcutaneous fat in relation to body build. It is well known that ordinary weight-for-height-and-age tables are liable to miss children with big frames and to include well-covered children with light frames. The starting-point of the new index was an investigation of over ten thousand children of varying social and economic status, scattered over seventy-five cities in the United States of America. A medical examination was combined with a complete set of measurements—shoulder breadth, hip width, chest width and depth, height, weight, arm and calf girth, size of deltoid, and thickness of the subcutaneous tissue over different areas of the arms and legs. A very thorough analysis was made of this material, and all sorts of combinations of measurements were tried. Some were found to yield no additional information to that given by other measurements, and they were discarded. Finally, the matter was narrowed down to a measurement of arm girth, chest depth, and hip width. Two instruments are needed—a steel tape and wooden callipers. The children are instructed to remove heavy clothing and empty their pockets. The upper arm is bared and only thin layers of clothing cover the chest. The girth of the upper arm is measured, first, with the arm flexed, at the highest point of the biceps, and, secondly, with the arm relaxed. The sum of the two measurements is called the "arm girth." Next the chest depth is measured with callipers placed just below the angle

of the left scapula, and, with the base of the callipers at right angles to the long axis of the chest, the other arm touches in front just above the nipple line. The measurements are taken at the end of inspiration and at the end of expiration with ordinary quiet breathing. The sum of these two readings is recorded as "chest depth." The "hip width" is next measured, and represents the distance between the most lateral parts of the great trochanters. The calculations now necessary consist in subtracting the sum of the two chest depth readings from the sum of the two arm girth readings. This is then compared in a table with the minimum difference allowed for each hip width. If the child is undernourished the difference will be less than that allowed in the tables. Tables for use with boys and girls between 7 and 12 years of age have been prepared. A higher rating can be used to pick out a larger number of cases for more detailed examination, but for general purposes the method and tables here described are recommended. A very thorough test of the "ACH index" was made for a group of 500 children aged 11 years, half boys and half girls. Out of this group, with the most extensive criteria available, forty-three children were selected as undernourished. Of these the "ACH index" picked out forty-one, as compared with sixteen by the ordinary weight-for-height method and twenty-seven with weight-for-height-and-width-of-hips. Rating by a medical examiner appears only to have detected five out of nineteen boys in the test, the rating for girls not being available. It is claimed that the method is very economical in time.

PRESCRIPTION OF THYROID: DANGER OF OVERDOSAGE

In a recent letter the Wholesale Drug Trade Association calls attention to an increased demand for 5-grain tablets of thyroid extract. Several firms, especially in the North of England, are now manufacturing twenty times as many of these 5-grain tablets of tab. thyroideum B.P. as they did before. It is thought that many practitioners are in the habit of inadvertently prescribing tab. thyroid. B.P. when they mean to order the considerably less potent *fresh* gland tablets. In support of this contention it is pointed out that several complaints have been received from doctors and chemists of untoward effects following the use of 5-grain thyroid tablets, and that on inquiry it has been found that the doctor had actually intended *fresh* gland to be used. The dose of the 1932 B.P. preparation "thyroideum" (synonyms: "thyroideum siccum," "dry thyroid," "thyroid extract," "thyroid gland") is given as 1/2 to 5 grains, and it should be realized that this preparation is five times as strong as the *fresh* gland preparation. The table of corresponding doses is given below:

Tab. Thyroid. Gland (Fresh).	Thyroid. Sicc. (B.P.)
1 1/2 grain	1/10 grain
1 "	1/5 "
2 grains	2/5 "
3 "	3/5 "
5 "	1 "

It seems opportune here to emphasize that when "thyroid tablets" are ordered *fresh* gland cannot legally be supplied. Consequently, unless *fresh* gland extract is specifically asked for there is a danger, almost a certainty, of the stronger extract being pro-

¹ The ACH Index of Nutritional Status. American Child Health Association, 480, Seventh Avenue, New York City. (10 cents.)

² Amer. Journ. Dis. Child., April, 1934, p. 789.

vided. In this connexion it is of interest to note that Martindale's *Extra Pharmacopoeia*, 1932 edition, states, under the heading of Standardized Thyroid Tablets: "We discard the old fresh substance basis for thyroid tablets as being unscientific and misleading. H. W. Paines repeats our advice . . . to prescribe [the drug] as *thyroideum siccum*."

JOHN KEATS'S ANATOMICAL AND PHYSIOLOGICAL NOTEBOOK

Every medical lover of Keats's poetry knows that he was a dresser at Guy's Hospital, that he qualified at the Apothecaries' Hall on July 25th, 1816, and that he actually practised for a short time. The little notebook in which he jotted down the substance of some of the lectures he heard as a student had long been known and, thanks to Sir William Hale-White, it was reproduced photographically.¹ Mr. M. N. Forman has done well to print the notes, even though in an edition of only 350 copies. He would have done still better could he have issued the whole book in facsimile, for the single page he reproduces makes one hunger for more. The notes in themselves are of small interest, for they only represent the anatomical and physiological teaching of the early nineteenth century. The value of the notebook lies in the delight it gives of seeing the script of one who wrote: "The other day during the lecture there came a sunbeam into the room and with it a whole troupe of creatures floating in the ray, and I was off with them to Oberon and fairyland." "My last operation," he once wrote to Charles A. Brown, "was the opening of a man's temporal artery. I did it with the utmost nicety but, reflecting on what passed through my mind at the time, it seemed a miracle, and I never took up the lancet again." Mr. Forman introduces the book with a short preface and a list of the persons to whom Keats refers. The "Mr. Grosvenor of Oxford" was John Grosvenor (1770-1817), a pioneer in massage, a founder of the Radcliffe Infirmary, where he was one of the earliest surgeons, and the proprietor and editor of *Jackson's Oxford Journal*. Dr. Gibson gives an excellent account of him in his *History of the Radcliffe Infirmary*.

THE JOURNAL OF THE A.P.I.M.

The May number of *Revue Internationale de l'Association Professionnelle Internationale des Médecins* contains matter of great interest and importance, including the questionnaires and answers on "the different legislations as regards accident insurance" and on "the legal and professional position of opticians." Full information on these subjects has been received from seventeen European countries. In a preliminary "Causerie professionnelle" the general secretary of the A.P.I.M., Dr. Fernand Decourt, takes up the question of "Abuse in sickness insurance," and, after dealing with the various allegations made as to the responsibility of the medical profession in this matter, which are "common form" in every country, he expresses the opinion that there are two reforms which, if adopted, might greatly lessen the claims for insured persons upon the funds of their societies. The first is that steps should be taken to give the insured

person a prospect of some pecuniary individual share in the financial benefit which would result from suppression of abuse. He is of opinion that if the insured person thought that he would have an individual claim on economies made, he would become a jealous defender of the prosperity of his society. Dr. Decourt quotes as evidence of this good result the existence of certain societies already making use of this method, which seems not unlike that adopted in this country by the Hearts of Oak Benefit Society. The second reform suggested by Dr. Decourt is that the insured person should participate in the expenses of the drugs and dressings supplied to him. This has already been done in one or two countries with considerable advantage, and those who are interested in this subject would do well to read what Dr. Decourt has to say about it. In addition, there are letters from the correspondents in Austria, Holland, and Poland, containing much interesting information as to the professional position in these countries.

SUMMARIES

Sir Clifford Allbutt, in his *Notes on the Composition of Scientific Papers*, gave the following advice: "On the completion of a long thesis or important scientific essay it is well to draw up a syllabus of the argument and to place it at the beginning; in any case let the conclusions be resumed succinctly at the end; it is not for the author to compel the reader to peruse his essay." Developing this point on rather more technical lines, Drs. George H. Simmons and Morris Fishbein wrote in their *Art and Practice of Medical Writing*: "The summary—a brief abstract of the article—may appear at the beginning or at the close. Not every article should be summarized. Those of more than average length (more than 1,500 words), those which involve much description of detail and technic, and those which aim at a complete survey of literature on the particular subject demand a summary. A brief digest of a long article in the introductory paragraph often will stimulate some to read the article who otherwise would not." Our object in making these quotations, as might be supposed, is to remind medical authors once again that every MS. except the shortest should be regarded as incomplete without a concise summary. Having quoted so much we may end with another extract. In her little book, *The Writing of Medical Papers*, Mrs. Maud Mellish-Wilson (whose death a few months ago is deplored far beyond the Mayo Clinic) advised contributors to scientific journals to wind up their articles with "a brief review of the work done and of the conclusions which may properly be drawn therefrom. The writer should have in mind that this portion of the paper is usually not only the first portion read, but that it may be the only portion read. Further, if properly made, the summary and conclusions may serve as a most desirable form of abstract to be published by other journals."

On the evening of Friday, June 29th, at the London School of Hygiene and Tropical Medicine (incorporating the Ross Institute), the Earl of Athlone, Chancellor of the University of London, will perform a ceremony in honour of the memories of Patrick Manson and Ronald Ross.

MEDICAL VISIT TO RUSSIA

MOSCOW CONGRESS ON RHEUMATISM

[FROM A CORRESPONDENT]

The Fourth International Congress on Rheumatism was held in Moscow, from May 3rd to 7th, and was attended by the delegates of no fewer than twenty-six nations. After the closure of the official Congress a party travelled to South Russia to inspect the medical arrangements of this part of the country and to view the spas and health resorts of the Caucasus and Black Sea regions. Another party, with less leisure, went to Leningrad, where they spent three days, returning home from there by boat.

SCIENTIFIC SESSIONS

The official opening was performed by the People's Commissioner for Health in the presence of over 2,000 persons, and the scientific sessions commenced with papers on the subject of rheumatism and the heart from the President of the Congress, Professor Konchalovsky, Dr. P. M. Weil (Paris), Dr. Coburn (New York), Professor Singer (Vienna), Dr. Bradley (England), Dr. Schlesinger (London), Professor Holsti (Helsingfors), Professor Kissel (Moscow), and others. An excellent pathological and therapeutic museum was then inspected in the "Hall of Savants," where the remaining sessions took place. During the afternoons sight-seeing tours were arranged for the delegates, who were able thus to visit the Kremlin, the tomb of Lenin, St. Basil's Cathedral, and other orthodox "sights." In addition, tours were made each day to the various fine physiotherapeutic clinics of Moscow, the children's hospitals, abortion clinics, big factories—each of which has a clinic and beds attached—and the Central State Institute of Hydrology and Climatology (Professor Danichevsky). On the following days the discussions centred round the subjects of the balneological treatment of chronic rheumatism and arthritis in miners, and transport and metal workers. Papers on these subjects were presented, among others, by Professors Plate (Hamburg), Connut (Prague), Vlastos (Athens), Dalmady (Budapest), and Pisani (Italy), and Doctors Fischer (Paris), Kahlmeter (Sweden), Fortescue Fox (London), Danichevsky (Moscow), Schmidt (Pistany), Copeman (London), and Buchstab (Odessa). On the first evening a banquet was arranged at the Hotel National for the delegates, whilst on the second night a special performance was given at the State Opera House. On the third evening, certain of the delegates had the unusual distinction of being entertained by Kalinin, the President of the U.S.S.R., to dinner in the Kremlin.

THE TRAVELLERS' LOG

The party who travelled southwards left Moscow on May 8th, and arrived at Kharkov, an industrial centre, halfway between Moscow and the Black Sea, in time for a late breakfast on the next day. Here, as elsewhere, they were met by a delegation from the State Public Health Ministry and from the local medical societies. They were shown round all that was most interesting from both the medical and lay sides, were entertained sumptuously, and then sent on their way to their next "port of call"—a large "collective" farm in the North Caucasus region. The distance traversed necessitated continuous night travel through the three weeks' duration of the tour, and proved somewhat fatiguing. It was, however, of the greatest interest to study the practical application of communism to medicine in a country of 170 million inhabitants. The result cannot, the English party thought, be yet judged either as a complete success or as a failure. It was felt, however, that, although a great deal remained to be done, much, nevertheless, had already been accomplished, particularly in view of the previous extreme backwardness of Russia in this sphere. A spirit of enthusiasm seemed to imbue the majority of the medical men with whom we talked, despite the very low standard of comfort enjoyed by these men in comparison with the standards of the West.

The further centres visited included Sochi, Gagri, and Sukhum, beauty spots on the Black Sea; two days on the Black Sea itself en route for Yalta and Sebastopol, in the Crimea; Odessa, where some of the party took the famous "Liman" mud baths; and, lastly, Kiev, the capital of the Ukraine, where a final banquet and performance at the Opera were provided after a day of energetic sight-seeing in almost tropical heat.

JOINT COUNCIL OF MIDWIFERY

The Joint Committee on Midwifery held its second meeting on May 30th, with the Earl of Athlone in the chair, and received the reports of the Training and Distribution and the Administrative Subcommittees appointed last January. Among those present were:

Sir Francis Fremantle, M.P., and Miss Megan Lloyd George, M.P.; Dr. J. S. Fairbairn and Mr. L. C. Rivett, representing the British College of Obstetricians and Gynaecologists; Mrs. Stanley Baldwin and Lady Williams, representing the National Birthday Trust Fund; Miss Pye, Miss Burnside, and Miss Carter, representing the Midwives' Institute; Sir William Hale-White and Miss Wilmshurst, representing the Queen's Institute of District Nursing; Miss Doubleday, representing the College of Nursing; Dr. W. H. F. Oxley, representing the British Medical Association; Miss Wooldridge and Miss Coleman, representing the Association of Inspectors of Midwives; Major Elton Longmore, and Dr. Newnham.

RESOLUTIONS ADOPTED

The report of the first subcommittee, under the chairmanship of Dr. Fairbairn, contained six resolutions (five of which dealt with technical matters), which will be referred back to the constituent bodies for their approval or amendment. The sixth, which was unanimously approved by the committee, was as follows:

"This committee is of opinion that a detailed scheme should be prepared for the enlistment of midwives throughout the country in an organized service, suited to the needs of each district, and having due regard to the retention of the mother's freedom of choice of attendant."

It was resolved that this resolution should constitute the terms of reference for the future work of the committee, together with the fourth and last resolution submitted by the Administrative Committee. The Administrative Subcommittee, under the chairmanship of Sir Francis Fremantle, had been examining the problem of the payment of the midwife's fee in necessitous cases, and submitted the following resolutions, which were passed unanimously, and will be referred back to the constituent bodies:

"That it be made compulsory upon local authorities under the Midwives Acts or the Maternity and Child Welfare Acts (1) To pay the midwives' fees in necessitous cases. (2) That the term 'necessitous' should be interpreted to mean that in computing all resources the whole of the maternity benefit, exclusive of any increase in such benefit by way of additional benefits and of any second maternity benefit, shall be disregarded. (3) That the manner of claiming her fee by the midwife shall be clearly defined and shall not necessarily entail application to and approval by the local authority before the birth."

"That in every case where for her safety the mother is removed to hospital the local authority should be required to make a payment to the midwife on an approved scale for such pre-hospital treatment as she may have carried out."

"That where the local authority have paid such fees they shall have power to recover unless it be shown to their satisfaction that by reason of poverty the patient is unable to pay such fee."

"The committee is of opinion that further consideration of the whole question of the remuneration of midwives as bearing on the efficiency of the midwifery service is urgently required."

The name of the committee was changed from "The Joint Committee on Midwifery" to "The Joint Council of Midwifery."

THE BIRTHDAY HONOURS

The Honours List, issued on the occasion of His Majesty's birthday, includes the names of the following members of the medical profession:

G.C.V.O.

Sir MILSOM REES, K.C.V.O., D.Sc., F.R.C.S.Ed., Laryngologist to Their Majesties the King and Queen.

K.C.M.G.

AMBROSE THOMAS STANTON, C.M.G., M.D., F.R.C.P., Chief Medical Adviser to the Secretary of State for the Colonies.

K.C.V.O.

MAURICE ALAN CASSIDY, C.B., M.D., F.R.C.P., Physician Extraordinary to the King.

K.B.E. (Civil Division)

FREDERICK GRANT BANTING, LL.D., M.D., D.Sc., of the Dominion of Canada, discoverer of insulin.

Knighthood

Major ROBERT GEORGE ARCHIBALD, C.M.G., D.S.O., M.D., R.A.M.C. (ret.), Director, Wellcome Tropical Research Laboratories, Sudan.

CONVNS BERKELEY, M.A., M.D., M.Chir., F.R.C.P., F.R.C.S., F.C.O.G., M.M.S.A., Consulting Obstetric Surgeon, *Middlesex Hospital, Director of the L.C.C. Radium Centre.*
GRAFTON ELLIOT SMITH, M.D., Litt.D., D.Sc., F.R.S., F.R.C.P., Professor of Anatomy in the University of London (University College).

Major-General JAMES DRUMMOND GRAHAM, C.B., C.I.E., K.H.S., I.M.S. (ret.), late Public Health Commissioner with the Government of India.

Rai Bahadur UPENDRA NATH BRAHMACHARI, Medical Practitioner, Bengal.

C.B. (Military Division)

Major-General PATRICK HAGART HENDERSON, D.S.O., M.B. (late R.A.M.C.), Honorary Physician to the King, Director of Hygiene, the War Office.

Major-General ERNEST ALEXANDER WALKER, M.B., F.R.C.S. Ed., I.M.S., Honorary Surgeon to the King, Director of Medical Services, India.

C.B. (Civil Division)

Surgeon Rear-Admiral PERCIVAL THOMAS NICHOLLS, M.R.C.S., L.R.C.P.

C.I.E.

Lieut.-Colonel JOHN ALFRED STEELE PHILLIPS, I.M.S., Director of Public Health, Bihar and Orissa.

Lieut.-Colonel HAROLD HOLMES KING, I.M.S., Director, King Institute, Guindy, Madras.

C.V.O.

LOUIS FRANCIS ROEBUCK KNUTHSEN, O.B.E., M.D.

C.B.E. (Military Division)

Group-Captain EDWARD CECIL CLEMENTS, O.B.E., M.R.C.S., L.R.C.P., R.A.F.

C.B.E. (Civil Division)

JOHN CROSTHWAITTE BRIDGE, F.R.C.S.Ed., M.R.C.P.Ed., D.P.H., Senior Medical Inspector of Factories, Home Office.

WILLIAM HENRY PEACOCK, M.B., B.Sc., Deputy-Director of Health Services, Nigeria.

O.B.E. (Military Division)

Colonel WALTER LISTER, T.D., M.R.C.S., L.R.C.P., late Assistant Director of Medical Services, 49th (West Riding) Division, Territorial Army.

O.B.E. (Civil Division)

HARRY EDWARD HEWITT, M.D., B.S., D.P.H., Second Medical Officer, General Post Office.

Miss KATHERINE STEWART MACPHAIL, M.B., Ch.B.Glas., Member of the British Community in Belgrade.

Khan Bahadur KHWAJA ABDUL RAHMAN, M.B., Ch.B.Ed., D.P.H., Director of Public Health, Punjab.

GEORGE MACLEAN, M.B.E., M.B., Ch.B., Sleeping Sickness Officer, Tanganyika Territory.

I.S.O. (Companion)

Rai Sahib LALA RAM SAHAI, Sub-Assistant Surgeon, Residency Hospital, Indore, Central India.

M.B.E. (Military Division)

Flight Lieutenant FRANCIS WILFRID PETER DIXON, M.B., B.S., R.A.F.

M.B.E. (Civil Division)

JOSEPH ANTOINE HERMANN ANDRÉ, M.R.C.S., L.R.C.P., Superintendent, Leper Asylum, Mauritius.

ANDREW BUCHANAN MACDONALD, M.B., Ch.B., for devoted work in the treatment of lepers in Nigeria.

JOSEPH LENNOX DONATION PAWAN, M.B., Ch.B., Government Bacteriologist, Trinidad.

Major FRANK HERMANN OTTO, Indian Medical Department, Assistant Surgeon on the Port Health Staff, Bombay.

GEOFFREY OSNUND SCHMIDT, Indian Medical Department, Assistant Surgeon, British Consulate, Kasigar.

SOWANI PUAMAU, First Native Medical Practitioner, Gilbert and Ellice Islands Colony, Western Pacific.

Hon. M.B.E. (Civil Division)

YUSUF HAJJAR, M.D., Medical Officer in charge of the Government Hospital at Jerusalem, Palestine.

Kaisar-i-Hind Medal (First Class)

Miss DORIS LOUISA GRAHAM, M.D., B.Ch., Medical Missionary, Krishnagar, Bengal.

Miss MILLICENT VERE WEBB, L.R.C.P. and S.Ed., L.R.F.P.S., F.C.O.G., Chief Medical Officer, Women's Medical Service, and Secretary of the Funds under the Presidency of Her Excellency the Countess of Willingdon.

LONDON AND COUNTIES MEDICAL PROTECTION SOCIETY

The annual general meeting of the London and Counties Medical Protection Society was held at Victory House, Leicester Square, on May 30th, with Sir JOHN ROSE-BRADFORD in the chair.

The chairman, in presenting the annual report, said that there was no very outstanding feature to which he had to call attention. There had been a notable increase of work during the past year, not only in the number of applications for advice received, but in the number of cases which had had to be seriously considered by the society. Fortunately, settlements had been arrived at in the large majority of instances and litigation avoided. He had again to lay stress on the importance of membership of a defence society; the fact still remained that something like one-third of the practising members of the profession appeared content to remain without this protection. He referred regretfully to losses sustained during the year, in particular by the deaths of Dr. E. Collier Green and Sir George Makins, vice-presidents of the society for twenty-three and seventeen years.

The report was adopted, and Sir John Rose Bradford was unanimously re-elected to the presidency. The vice-presidents were also re-elected, with the addition of Sir William Hale-White and Sir Cuthbert Wallace, as were the retiring members of council, the secretary (Dr. C. M. Fegen), and the treasurer (Dr. R. L. Guthrie). In speaking to one of these resolutions Dr. C. O. HAWTHORNE said that it was really astonishing when one read the annual report how any member of the profession could comfortably sleep at night unless he had the protection of a defence society. The British Medical Association never lost an opportunity of urging newly qualified practitioners to join a defence society as one of their first acts after registration. The report showed also that it was advisable even for those of riper years to maintain their association with such a body, because new points of attack continually appeared to which no one's attention had ever been drawn before. The meeting concluded with votes of thanks to the officers, legal advisers, and staff.

THE SOLICITORS' REPORT

The solicitors' report, which was embodied in the general report of the society, urged that the present relation of insurance practitioners to the Ministry of Health in the matter of prescribing appeared to need revision. The insurance practitioner was between the devil and the deep sea. If he failed to prescribe adequately he was liable to be brought before the medical service subcommittee on a charge of having failed to render all necessary and proper services; if he prescribed what in his opinion were the best drugs, his average might be above the average for the area. One piece of legs

lation during the year would be of great value to the medical profession in High Court proceedings. Prior to the passing of the Administration of Justice (Miscellaneous Provisions) Act, 1933, every litigant had the right to ask that his action should be tried by a jury, but that right, save in certain specified cases, had now been taken away. In the past patients instituting proceedings against medical men had, for obvious reasons, asked for a jury, and there were no grounds for opposing the trial of a jury action. It had sometimes been found that, despite the evidence, a jury had returned a verdict for the patient, evidently moved by motives of sympathy, and once it was found by a jury that a doctor had been guilty of negligence the verdict was practically impossible to upset. By the passing of the Act a number of these difficulties would be removed. The solicitors further mentioned that the wider use of psychological treatment increased the risk of attack by patients, particularly women, upon practitioners in this field. There were a large number of cases in which women patients had made the most extraordinary accusations against the doctor treating them. It was a risk inherent in this type of treatment: the need for safeguard through membership of a defence society was again emphasized.

SHENLEY MENTAL HOSPITAL

OPENING BY THE KING

The Middlesex County Mental Hospital at Shenley, in Hertfordshire, was opened by the King, who was accompanied by the Queen, on May 31st. A description of the new hospital, which is situated in grounds of about 500 acres, appeared in these columns of February 10th (p. 257).

Their Majesties, on arrival, were received in a marquee by Viscount Hampden, Lieutenant for Hertfordshire, who presented Mr. Howard S. Burton, chairman of the Middlesex County Council, Sir William Lobjot, chairman of the Hospital Visiting Committee, and Mr. L. G. Brock, chairman of the Board of Control. A move was then made to the recreation hall, a large building constructed for stage and cinema performances, with seating accommodation for 1,000, where Sir William Lobjot read an address of welcome. He said that this institution was the first public mental hospital to be designed and opened since the war. The cost of its erection was over half a million. The present buildings accommodated 1,046 patients—the ultimate accommodation would be 2,000—and the detached villa plan had been adopted so as to facilitate the classification and treatment of patients in comparatively small groups on the most modern scientific principles. The reception hospital, which was fully equipped for intensive medical investigation, and the adjacent convalescent units were specially designed for the treatment of early mental illness. In this connexion the provisions of the Mental Treatment Act, 1930, had been borne in mind, particularly the enlargement of the opportunities for voluntary treatment. Every facility was available for the occupation and recreation of patients, both in the recreation hall and in the ample grounds.

The King, after expressing the pleasure of the Queen and himself at the opening of the hospital, and their interest in the mental health service, continued: "In recent years important advances have been made in the ideas governing the treatment of mental illness, and the Act to which you have referred has enlarged the opportunities for applying these new methods. It is necessary that such progress should be reflected in the provision which local authorities make for the mentally afflicted under their care. I note with satisfaction that, in designing this mental hospital, you have paid special regard to the treatment of early mental illness by the provision of the reception hospital, which I look forward to seeing to-day. I am glad that you have provided a nurses' home. Such provision not only contributes to the contentment and well-being of the nurses, but has a profound influence upon the recruitment of this important branch of the hospital staff. I congratulate the Middlesex County Council, the Visiting Committee, and the Board of Control upon the manner in which this important enterprise has been conceived and carried out."

After the King had declared the hospital open dedicatory prayers were said by the Bishop of St. Albans, and the members of the committee, the medical superintendent (Dr. G. W. Shore), the matron, and other officers were presented. The King and Queen then inspected certain parts of the hospital, including the kitchen, the reception hospital, and the nurses' home, signed the visitors' book, and took their departure, after which there was a general inspection by the guests. The hospital has its own water supply, sewage treatment works, lighting plant, and various other services, for the distribution of which three and a half miles of underground subway has been constructed. It is fully equipped with operating theatre, dental and other clinics, x-ray and special treatment rooms, dispensaries, and laboratories. Residences have been provided for the medical superintendent and deputy medical superintendent, and houses for assistant medical officers, senior officials, and a staff village form part of the ultimate scheme.

Scotland

New Chairman of Scottish C.M.B.

At a meeting of the Central Midwives Board for Scotland, held on May 31st, Dr. Robert Cochran Buist, consulting gynaecologist to the Dundee Royal Infirmary, was appointed chairman of the Board in succession to the late Dr. James Haig Ferguson. Dr. Buist is a graduate of Cambridge, St. Andrews, and Edinburgh Universities, and in 1932 received the honorary degree of LL.D. from St. Andrews. He is a vice-president of the British Medical Association, and was at one time a prominent member of Council, deputy chairman of the Representative Body, and chairman of the Journal Committee. He has been an active member of the Scottish Committee of the Association, and served for some years as its honorary secretary.

Edinburgh Royal Infirmary

The last annual report by the managers of the Royal Infirmary of Edinburgh recalls that from early times this institution has profited very greatly from the large sums bequeathed by means of legacies. An indication of the deep hold of the Infirmary on the affections of Scottish people at home and abroad is afforded by the announcement that during the year under review bequests were intimated from South Africa, the United States, Canada, India, and Greece, while the occupations of the testators included those of a gamekeeper, a farm labourer, a quarryman, a domestic servant, and a nurse. The amount received for general purposes and endowment was £56,247. In addition, a legacy of £4,500 was received for cancer research, and is being applied primarily for assisting work in the radium and x-ray departments. The ordinary income was maintained; there were increases in patients' donations, contributions from approved societies, and payments by insurance companies under the Road Traffic Act, but a reduction in interest and dividends from invested funds is likely to be still more serious this year. The Infirmary extension scheme has been carefully reviewed in the light of present conditions. It was discovered that the original proposals to erect a combined gynaecological and maternity hospital, together with a home for nurses, would cost very much more than the amount which had been collected or was likely to be collected in the immediate future. It was decided, therefore, to restrict the scheme to a maternity hospital and the building of a new nurses' home. The Board of the Infirmary was already committed to build a new maternity hospital by the agreement entered into with the directors of the existing Edinburgh Royal Maternity and Simpson Memorial Hospital. Provision is made for 122 beds, with departments for all sections of maternity work,

including facilities for the instruction of medical students and midwives. The new nurses' home will give accommodation for 260 nurses. It is proposed to erect this building on a site to the north of the new maternity hospital, partly on the site of the former George Watson's College, and partly on ground acquired at the foot of Archibald Place. Even with the restriction of the scheme it is anticipated that the capital cost will exceed the available funds by between £40,000 and £50,000, so a further appeal will have to be launched. Construction of the new pavilion to house the skin and venereal diseases departments on a site to the north of the eye department is proceeding. When complete, this addition will set free for other purposes valuable accommodation in the main building.

Lord High Commissioner in Edinburgh

His Grace the Lord High Commissioner, Mr. John Buchan, who represents the King at the annual Assembly of the Church of Scotland, has made his usual round of visits to hospitals in Edinburgh. Accompanied by Mrs. Buchan, he paid a visit to the Royal Infirmary on May 23rd. In presenting prizes won by nurses in the recent examinations, Mr. Buchan remarked that he had made up his mind that he would write a medical book, because he wished to know more about medical science, and from long experience he knew that the way to find out more about a subject was to write a book on it. Mrs. Buchan on the same day paid a visit to the Queen's Institute for District Nursing, where she was received by Lady King Stewart, representing the Scottish Council, who informed her that there were now 503 affiliated nursing associations in Scotland, employing 895 nurses. On May 24th a visit was paid to the Deaconess Hospital of the Church of Scotland, which, as Mr. Buchan recalled, is the only hospital in Britain owned by a Protestant Church. He made reference to the loss the hospital had sustained in the recent death of its chairman, the late Lord Sands, who, he said, had been a man of many-sided interests. The proposed extension of the hospital, he had been informed, was to be called the Lord Sands Memorial Wing. Mrs. Buchan paid a visit also to the Royal Maternity and Simpson Memorial Hospital, where she made a tour of the wards and inspected the seventy babies at present in the hospital.

Conference of Health Visitors

The Scottish National Health Visitors Association, to the number of nearly 200 delegates and members, held its fifteenth annual conference last month at Kilmarnock. After a civic welcome by Provost Henry Smith, a paper dealing with maternal morbidity, by Dame Louise McLroy, was read by Dr. Arbuckle Brown, deputy medical officer of health, Glasgow. This was followed by an address by Professor Munro Kerr, who said that maternal morbidity and mortality were influenced by three primary factors—the adequacy of ante-natal care, the efficiency of natal care, and the degree of co-ordination between the different agencies concerned with maternal care. Many of the unsatisfactory conditions at present connected with ante-natal supervision would automatically disappear if the agencies concerned with maternal welfare were better co-ordinated. For many years, Professor Munro Kerr said, he had advocated a maternity service for the country, and to-day everyone admitted that a maternity service in some form was essential for insured persons, for those who would become insured if the Insurance Act was extended, and for the destitute. The idea underlying his scheme was the establishment of a network of obstetric centres throughout the country, utilizing existing institutions

and making additions where necessary. In the scheme he proposed the institutional part of the service for Scotland would consist of: (1) four primary hospital centres in Edinburgh, Glasgow, Aberdeen, and Dundee; (2) secondary hospital centres in towns and in cottage hospitals; and (3) subsidiary centres at maternal and infant welfare clinics, which ought to be closely linked with the hospitals of the locality and the centres for its domiciliary service. The activities of family doctors, midwives, health visitors, and social workers should be based on these centres and clinics, which, in addition to their purely medical function, would be invaluable centres for the training of the last three groups of workers. Dr. B. R. Nisbet, medical officer of health, Kilmarnock, said that a careful inquiry had shown that in Kilmarnock 81 per cent. of the mothers had some ante-natal care, while in 50 per cent. it was considered adequate. These figures were, comparatively speaking, good, though not ideal, and perhaps explained the fact that out of 1,500 births in the town during two years there had been only two maternal deaths. The maternity home had rendered good service, but was now too small to cope with the needs of the district, and it had been decided to build a new maternity hospital, which would maintain the close existing relation of the practitioners in the district with the official maternity scheme.

Selkirk Hospital

The annual meeting of Selkirk Cottage Hospital Association was held on May 31st, when it was announced that the endowment fund stood at £12,277, while there was a balance to carry forward to next year out of which the committee recommended that £500 should be transferred to the endowment fund. It was reported that during the year 231 patients had been treated under the scheme, and that there had been 134 private patients.

Ireland

The State and the Practice of Medicine

Dr. Charles S. Thomson, medical superintendent of health, Belfast, in the course of a paper read at the Royal Victoria Hospital, stated that a question which was giving concern to many people was the question of whether the practice of medicine, and this included the hospitals, was to be governed by the State, in whole or in part, or not at all. The mere mention of putting the voluntary hospitals on the rates, for example, was sufficient to arouse a commotion within the breasts of thousands, for it was widely held that the splendid work of the voluntary hospitals was largely due to the freedom which, in itself, made for the success of those institutions. It was held that the very soul of the hospitals would be destroyed if the recalled cold, formal hand of the State replaced the close, personal touch which resulted from the voluntary system. Someone has said that a bank overdraft was a sign of wealth. Assuredly it conveyed the idea that the bank had good security before it parted with its money. In the case of the British hospitals the banks knew that there was excellent security in the profound respect and esteem in which the hospitals were held by the public, and that, in the last resort, notwithstanding the financial difficulties of the times, the public might be relied upon to see the hospitals through. They could therefore put aside any question as to whether a threat of State supervision of the voluntary hospitals was imminent. The question of the financial needs of their hospitals was one which sound organization, push, and drive ought to settle.

Public Health in the Irish Free State

Moving the recent vote in the Dáil for the Department of Local Government and Public Health, the Minister, Mr. S. T. O'Kelly, said that during the year mortality from all causes showed a reduction as compared with the preceding year. The number of deaths registered in 1933 was 40,650, as against 42,984 in 1932. Deaths from typhus numbered twelve, as compared with thirty in the preceding year; and from enteric fever sixty-nine—a reduction of thirteen. There was a welcome decrease in infant mortality. The number of deaths was sixty-five per 1,000 registered, as compared with seventy-two per 1,000 in 1932. The prevalence of diphtheria showed a serious upward tendency, the number of deaths being 414 as against 383 in the previous year. Measures for the immunization of children against the disease, however, were being widely adopted. The organization of public health services was proceeding satisfactorily. Child welfare schemes were being well maintained, while schemes for school medical inspection were now practically complete in the four county boroughs and in eighteen counties in which county medical officers of health were in charge. The number of children inspected by the school medical officers in 1932 was 112,776; the figure for 1933 was not yet available. Of the number examined in 1932, 37 per cent. were found to suffer from dental defects, 22 per cent. from tonsils and adenoids, 11.9 per cent. from defective vision, 3.9 per cent. from other eye defects, and 6.2 per cent. from malnutrition. These figures represented a decline as compared with those for 1931, except in the case of children suffering from dental defects. Great interest continued to be taken in this service by school managers, teachers, and parents of the children. In practically every case the advice of the county medical officer of health in regard to proper dieting had borne good results, and the number of children suffering from malnutrition was on the decline. The provision of free milk, for which a sum of £100,000 was included in the estimate, had helped largely in this respect. Dr. R. J. Rowlette, speaking during the debate, said he believed that the Minister was honest and earnest in his desire that public health administration should be improved, but there were various matters in which progress during the past year or two had been disappointing. Since 1925 it had been the law of the country that each county authority should appoint a county medical officer of health, but, in reply to a question a few days ago, the Minister had informed him that there were only eighteen such officers appointed in the twenty-seven county areas in the country, and, when pressed, the Minister had said that some of the county authorities had not enforced the law because of unwillingness to increase local rates. It was not, however, a matter of choice for county authorities. The law was there and should be obeyed; the Minister should take some action. The country, as the Minister must be aware, was far behind others in public health administration. Then, in the matter of medical inspection in schools, although the Act had been in force since 1919, only 30 per cent. of the children were being medically inspected. Infant mortality was increasing in the cities throughout the country. Every county, Dr. Rowlette continued, should have its infant welfare society. In 1932 the death rate in Galway of infants under the age of 12 months was 136 per 1,000 births registered, whereas the rate for the whole country was only 71. The rate in Waterford City was 132, in Sligo 134, and in Wexford 113. In Dublin, where there was a child welfare association, the rate was only 100. The Ministry should be far more active in encouraging the formation and development of such societies. He welcomed the report, which showed that the death rate from tuberculosis was the lowest on record.

There had been a steady growth in the prevention and treatment of tuberculosis in Ireland for the last twenty years, and he was glad to see that it was bearing proof. But surely, with such striking evidence, the Minister could bring sufficient pressure to bear on the county of Longford to make the authorities provide for the treatment and prevention of tuberculosis as other counties had done. Referring to the question of pure milk supply, Dr. Rowlette said it was estimated that at least 50 per cent. of the cases of tuberculosis, other than tuberculosis of the lungs, were due to contaminated milk. Deaths under this heading for the year 1932 numbered 818, so that 409 deaths were due to the fact that the Oireachtas had neglected to do its duty in ensuring a pure milk supply. To those deaths could be added an enormous amount of illness and disability due to dirty milk. Why had the long-promised Clean Milk Bill not been introduced?

Medical Charity: Bequest by Sir William Whitla

The managing committee of the Royal Medical Benevolent Society in Ireland has acknowledged the receipt of £250, a legacy bequeathed by the late Sir William Whitla. By the terms of his will this sum is to be invested, and the income applied to medical men in Belfast, or their wives, and orphans in Northern Ireland. Sir William Whitla was a keen supporter of medical charities, and this legacy is typical of his generosity.

England and Wales

The Drought

Speaking at Swindon, on June 1st, on the occasion of the opening of the new water scheme, Sir Hilton Young described the measures being taken by the Government to relieve the drought, which existed, he said, over a large part of Northern Europe and America; unfortunately we were in the middle of it. The recent fresh period of dry days made it more necessary than ever to take every possible precaution in anticipation of the summer months, which were usually the driest. The emergency Act which came into force last month provided the necessary legal powers to increase and husband supplies, and the Government was pressing forward with the application of the Act in order to deal with the situation in the places where there was already, or would probably soon be, a shortage. Sir Hilton was arranging for a standing conference of the three representative bodies—the British Waterworks Association, the Institute of Water Engineers, and the Water Companies Association—to act in co-operation with the Ministry. They would thus bring to bear upon remedial measures all the available knowledge and experience of the experts and of those actually responsible for water supplies. The measures that were being taken would be effective in reducing the evils of the drought. Much could be done by the public for its own protection by economizing the use of water for domestic and industrial purposes by preventing waste and by reducing use for all purposes that were not essential.

Ministry of Health Circular on Birth Control

By direction of the Minister of Health a letter (Circular 1408) has been sent to maternity and child welfare authorities in England and Wales on the subject of birth control. This begins with a reference to the Ministry's memorandum (153/M.C.W.) dated March, 1931, and Circular 1208 of July 14th, 1931, and more particularly to paragraph 4 of the memorandum and paragraph 3 of the circular which deal with the provision under the Public

Health Acts of clinics for women suffering from gynaecological conditions. Paragraph 4 of the memorandum stated that the Government had decided that any Departmental sanction which might be necessary to the establishment of such clinics should be given only on condition: (1) that the clinics will be available only for women who are in need of medical advice and treatment for gynaecological conditions, and (2) that advice on contraceptive methods will be given only to married women who attend the clinics for such medical advice or treatment, and in whose cases pregnancy would be detrimental to health. The present circular (dated May 31st, 1934) recalls that the Departmental Committee on Maternal Mortality and Morbidity, in its final report published in 1932, called special attention to the importance of the avoidance of pregnancy by women suffering from organic disease such as tuberculosis, heart disease, diabetes, chronic nephritis, etc., in which child-bearing is likely seriously to endanger life. The Departmental Committee considered that advice and instruction in contraceptive methods should be readily available for such women. It was pointed out in the memorandum and circular of 1931 that the powers which the Public Health Acts confer upon local authorities for the provision of clinics limit their availability to sick persons, but the Minister is now advised that there is nothing to prevent the local authority from rendering such a clinic available for women suffering from forms of sickness other than gynaecological conditions. After careful consideration of the recommendation made by the Departmental Committee, the Minister is of opinion that where a local authority has provided a clinic at which medical advice and treatment are available for married women suffering from gynaecological conditions, and at which contraceptive advice is afforded to married women so suffering in whose cases pregnancy would be detrimental to health, it would be proper also for married women who are suffering from other forms of sickness, physical or mental, such as those mentioned in the Departmental Committee's report, which are detrimental to them as mothers, to be afforded contraceptive advice at the clinic if it is found medically that pregnancy would be detrimental to health. "What is, or is not, medically detrimental to health must be decided by the professional judgement of the registered medical practitioner in charge of the clinic."

Radiologists at Dinner

The annual dinner of the Section of Radiology of the Royal Society of Medicine took place at Claridge's on June 1st, with Dr. R. S. Paterson in the chair. The principal guests were Dr. Robert Hutchison, president-elect of the Royal Society of Medicine, and Mr. W. H. Collins, donor of the munificent gift of £35,000 to the Middlesex Hospital, earmarked for the equipment of the diagnostic section of the radiological department. Dr. Paterson, in proposing the health of the guests, referred to Mr. Collins as a man whose generosity was united to vision. He was one of those who believed in the continuance of the voluntary hospital system, the only disadvantage of which was its financial limitations compared with State or municipal provision. By his beneficence he had enabled the radiological department at Middlesex to combine the enormous advantage of voluntarism with an unusual freedom from financial difficulty. Mr. Collins expressed the hope that the workers in the radiological departments of other hospitals would not be jealous of the good fortune of the Middlesex, but would rather invoke it as an example to their own boards and supporters. He congratulated the department on having Dr. Graham Hodgson in charge, saying how admirably Dr. Hodgson had collaborated with him in ensuring the best use of the help he had been able to furnish. Dr.

Robert Hutchison, in proposing the health of the Section, said how much he owed, as a dietitian, to the confirmatory (or otherwise) work of the radiologists, though he viewed them rather as a judge in the lower court must regard their lordships of appeal: they had a way of upsetting one's best clinical diagnosis. A distinguished physician once told him that when he had to recommend the removal of an appendix but was not very sure on the subject he was careful to send the case to a sympathetic surgeon. Dr. Hutchison confessed that he also liked to send his cases to a sympathetic radiologist, who would let the poor physician down lightly when he proved to be wrong. The Section of Radiology appeared to be very vigorous; it represented one of the advancing lines of medicine, and was taking to itself more and more diagnostic resources and wider facilities for treatment. Dr. Hernaman-Johnson mentioned that although the Section in its present form was only three years old, it was one of the largest of the twenty-odd Sections of the Society, numbering some three hundred members—the largest Section of all, the Clinical, having four hundred.

Infants Hospital, Westminster

Prince George took the chair at a festival dinner, on May 30th, in the Guildhall, in aid of the Infants Hospital, Vincent Square, the company numbering more than 400. At the close of the evening the Prince announced that contributions to the special appeal fund totalled £19,000. Among those at the high table were the Lord Mayor of London and the Lady Mayoress, Dr. Eric Pritchard, medical director of the hospital, Dr. G. F. Still, and Dr. H. Morley Fletcher. In proposing the toast of "The Hospital" His Royal Highness conveyed the regret of the Princess Royal at being unable to be present on behalf of an institution in whose welfare she, as its president, took a very keen interest. He recalled that this was the first hospital in the world whose special object it was to care for children under 5 years of age, and that large sums of money had been spent with much thought in bringing the hospital up to its present well-equipped position. Everything required in a modern hospital had been installed in miniature. The research work unceasingly carried out was providing most valuable data, and through this there was a continuous improvement in nursing and in treatment, to the advantage of many sick children all over the country. "If the present knowledge of infantile diseases had been available twenty-five years ago I feel sure that many C3 men and women would be classed A1 to-day." Sir Gomer Berry, chairman of the Committee of Management, in responding to the toast, said that the hospital now had 100 cots in Vincent Square and eighteen at the convalescent home at Burnham, while the out-patient department could accommodate 2,000 cases a month. After thanking Prince George for the honour he had conferred on them, he paid a tribute to the medical and surgical staff, under the guidance of Dr. Pritchard, whose work for the health of children was widely known and appreciated. Sir Ernest Benn submitted the toast of "The Lord Mayor and the Corporation of London," and Sir Charles Collett replied. Dr. Cyril Norwood, head master of Harrow, in proposing "The Citizens of To-morrow," looked forward to a system of physical education to which as much care and thought would be given as had hitherto been applied to purely mental education. Mrs. Stanley Baldwin, who replied, said that to save the children they must begin with the mothers. Foreign countries, and notably Italy, realized how much their future depended upon the younger generation. The medical, nursing, and administrative staff of the hospital were toasted by Sir Harold Bellman, and Dr. Eric Pritchard replied.

Reports of Societies

CONTROL OF INFECTIOUS DISEASES

At a meeting of the Society of Medical Officers of Health, held at their house on May 25th, with Dr. CHARLES PORTER in the chair, Dr. H. STANLEY BANKS, medical superintendent, Park Hospital, London, opened a discussion on "Current Methods of Control of Infectious Diseases."

Dr. Banks critically reviewed the main conclusions of Report No. 35 of the Ministry of Health on scarlet fever. The report favoured limitation of the number of scarlet fever cases admitted to hospital, and the preferential admission of pneumonia, measles, and influenza. This had been tried, particularly in London, but there was still an insistent demand for hospital facilities in scarlet fever. An alternative method was to shorten the period of detention in hospital to two or three weeks. This had been found to be quite practicable in the great majority of cases which were treated adequately with scarlatinal antitoxin at an early stage of the disease, and particularly by the intravenous route. Complications were then very few, and almost entirely limited to children under 5 years of age, who were susceptible to mixed infections. Short detention in scarlet fever wards was in the interest of the patient, provided that nutrition was maintained from the outset. Late complications in scarlet fever wards were probably often the result of superadded infection from patient to patient. It was desirable to combine short detention with attendance at an out-patient clinic at least once before the patient returned to work or school. This method had, in his experience, given satisfactory results. He agreed with the report in condemning terminal disinfection of houses and wards as an ineffective procedure. Current disinfection of hands and fomites during the illness was the important matter. This subject had been discussed *ad nauseam*, and the modern view was accepted by most authorities. He suggested that the time had come to make it public.

Dr. E. H. R. HARRIES, dealing with diphtheria, said that this was a preventable disease, only to be controlled adequately by the active immunization of susceptible children. The disease was prevalent and severe in this country at the present time, and it was to be hoped that immunization upon a scale sufficiently great to affect incidence might not be unduly delayed. Many cases of severe clinical type were associated with either the *gravis* (starch-fermenting) or *intermediate* (Mair's barred form), strains originally described by the Leeds workers. The swab, used as a primary or chief means of diagnosis, frequently resulted in fatal delay in the injection of antitoxin, and in the erroneous diagnosis of diphtheria in patients harbouring non-toxic organisms. Patients should be sent into hospital upon suspicion without swabbing, the necessary investigations being left to the hospital to carry out. Practitioners were reluctant to inject antitoxin pending diagnosis. Fears of anaphylaxis, especially with modern, practically protein-free, concentrated sera, were greatly exaggerated. Severe reactions, even with massive intravenous dosage, were extremely rare, and were controllable by the injection of adrenaline, which should always be available. Post-tonsillectomy diphtheria and scarlet fever might be obviated by the prior injection of a combined prophylactic dose of diphtheria and scarlet fever antitoxins. Preliminary Schick and Dick tests were preferable, as these would indicate which, if any, of the specific sera were called for. The value of terminal swabbing was problematical. The ordinary standard was two consecutive negative swabs from nose and throat. Chronic carriers nearly always had some nasopharyngeal abnormality which called for rational surgical measures. True intermittency of the carrier state among diphtheria convalescents nursed in open wards was rare. The apparent intermittency was frequently due to contact reinfections. Convalescent carriers were best treated in cubicles or in the open air. Swabbing as a means of detection of carriers

in the community was hopeless, but found its legitimate uses in the control of outbreaks in institutions when combined with virulence tests and Schick tests.

Dr. W. GUNN, in opening the discussion on measles and whooping-cough, mentioned some of the clinical and epidemiological features of these infections in the search for more rational and effective measures for their control. He referred to the great increase of facilities for hospital treatment and the wider provision for domiciliary care of measles cases by various health authorities and agencies within recent years. He exhibited charts detailing the numbers of measles patients admitted to the infectious diseases hospitals of the late Metropolitan Asylums Board and of the London County Council during the years 1924-34, and the numbers of contacts injected with immune measles serum during the last two epidemics, showing a steady increase of those two measures for measles control. While a great future was predicted for the general employment of immune serum in the prevention and attenuation of measles, the benefits of routine hospitalization of measles cases were probably overrated. To justify the expenditure of much public money and energy it was necessary to show that hospital treatment gave much better results than those following domiciliary care. Bacteriological evidence was brought forward to prove that the majority of the complications of measles were due to invasion by the haemolytic streptococcus, transmission of which from patient to patient was readily traceable, especially when they were nursed in ordinary "open" wards. He urged the general application of "bed-isolation" principles to the nursing of all cases of measles in the early stages of the disease, pointing out that the problem of "cross infection" was thereby largely solved. The sole exception to this was chicken-pox, ward outbreaks of which were readily controlled, as it was usually possible to identify the immunes and isolate the rest in appropriate wards. The frequency with which cross infection was directly attributable to exposure in the waiting rooms of practitioners and the crowded waiting halls of general hospitals, and measures for checking it, were mentioned. The therapeutic and prophylactic employment of various immune sera—measles, adult and convalescent, streptococcal and diphtheritic—in averting the most dreaded complications and secondary infections associated with measles was briefly discussed. Definite benefit appeared to follow the intravenous administration of immune measles serum when given in the early phases of the disease. Our measures for the control of whooping-cough, curative and preventive, remained unsatisfactory both for the individual and for the community. Routine administration of so-called specific drugs was unnecessary, and even harmful. Drugs should be reserved for cases where indications were present calling for their exhibition. Vaccines prepared from the Bordet-Gengou bacillus had proved useless—and occasionally dangerous—in treatment, but there was room for an extended investigation into the efficacy of a reliable vaccine in the prophylaxis of whooping-cough, such as had been carried out in America and Canada and on the Continent. In this country many workers had had adequate experience of the most approved methods of control of measles and whooping-cough, but, so far, the necessary administrative machinery and driving force had been lacking. Little real progress could be expected unless the various public health and hospital authorities joined hands in a resolute endeavour to stamp out the more serious acute infectious diseases.

On May 24th the Mayor of Middlesbrough opened the new municipal hospital for children at Holgate. The buildings were transferred from the late board of guardians in 1930, and have since been converted for their new use at a cost of about £2,500. Provision has been made for eighty-two beds, the acute cases being warded on the ground floor of the two-story building. There is also a schoolroom, and arrangements are made for the teaching of children with chronic diseases in the wards. An up-to-date operating theatre and an anaesthetic room are placed on the first floor.

CORRESPONDENCE

Psychological Effect of Hysterectomy

SIR,—I should very much value a discussion on the results of hysterectomy, partial or total, in your journal. One has been taught that the removal of the uterus has no effect, psychological or physical, on the woman, but I know of two cases where the effect was profound.

Case 1.—A woman of 33 was found to have a large fibroid. The surgeon told her that it might be possible to do a myomectomy, but advised partial hysterectomy, which was duly performed. The ovaries were left untouched. About six months later the patient began to suffer from profound depression, which reached its acme at the times when the menstrual period would normally have occurred. For over a year she was almost an entire nervous wreck, but gradually improvement set in, and she got over the acute breakdown. To-day, six years after the operation, she still is somewhat neurasthenic, and says she feels quite definitely that she has changed completely in character, and that the operation has had a profound psychological effect. I may add she has since married and has a satisfactory marital relationship. She is an extremely well-educated sensitive woman.

Case 2.—A married woman, aged 39, with two children, was advised partial hysterectomy for excessive periods due to fibroids. In this case the patient's reactions to the operation were not so marked, but she found that her normal sexual response to her husband had disappeared. This in itself might have been enough to agitate her seriously, but, in addition, the husband, an intelligent, well-educated man devoted to his wife, found that the idea of the absence of the uterus aroused such a distaste in his mind that he became impotent. His feeling of affection in no way changed, but the whole marital relationship was completely wrecked.

Both these instances seem sufficiently important to me to indicate that research into the matter might be extremely valuable. It appears that in the first case myomectomy would have been far preferable and should have been done. In the second case, I know that the patient to-day would infinitely prefer the inconvenience of menorrhagia and be as she was before to the sense of mutilation and shipwreck of her married life which she has now.

One knows that there are cases when hysterectomy is inevitable, but it does seem to me that the operation should be the final resort, and the pros and cons weighed more carefully than they are to-day. As a woman I feel that hysterectomy is bound to have a most profound psychological effect.—I am, etc.,

WINIFRED COPPARD, M.R.C.S., L.R.C.P.

Walberswick, Suffolk, May 28th

Diverticulitis and Diverticulosis

SIR,—In an interesting paper on the surgical aspects of diverticulitis, in the *Journal* of June 2nd (p. 973), Mr. Harold C. Edwards writes:

"On the history, the physical examination, and the x-ray findings, it may be impossible to distinguish diverticulitis from diverticulosis, except in the severer cases, and I have failed in my attempt to estimate the percentage of cases of diverticulosis in which inflammation occurs."

This can, of course, be true, but may I state that with careful radiology the diagnosis in early cases between diverticulosis and diverticulitis is, in our experience, easy, as soon as, say, an inch of the bowel wall has become involved in the oedema from adjacent inflamed pouches. First, the large jagged appearance of a diverticulitic area is characteristic; secondly, peristalsis can be observed to cease at that place; and thirdly, such an area does not undergo the continual changes in outline which healthier

parts do, whether dotted with diverticula or not—changes which are easily shown by superposing successive films. The jagged palisade appearance is also distinct from that of spasm without organic lesion, of growth, or of the pre-diverticular state. Difficulty in diagnosis may, of course, arise, but is usually confined to the somewhat rare advanced and complicated cases. The essential is to obtain the piece of bowel concerned in profile, if possible from more than one aspect.

Pictures demonstrating the above points, with clinical records, have been published by Mr. Marxer and myself (*Quart. Journ. Med.*, October, 1925; *British Medical Journal*, January 23rd, 1926; and *Lancet*, May 21st, 1927).—I am, etc.,

Ruthin, June 2nd.

EDMUND SPRIGGS.

Periodic Health Examinations

SIR,—In his lecture "Cancer: with Special Reference to Early Diagnosis," printed in the *British Medical Journal* of May 19th (p. 881), Dr. Roy Ward points out the value of periodic health examinations for the early diagnosis of cancer and the merits of life insurance companies in this line. "In the U.S.A.," he says, "life insurance companies give free examinations biannually to all life policy holders over 40." And at the same time he wishes such a system could be instituted in other countries.

May I first of all mention that it is not quite as good in America as Dr. Roy Ward thinks. Examination is not offered to all insured persons over 40, nor is it given biannually, even when it takes place. It depends on the sum of insurance taken out at what intervals the examination occurs: for low sums it is a five-year interval; for large sums a yearly one. The age is not limited; but no company grants the periodic examination to all policy holders. Then there are two English companies which grant such examinations—the "Legal & General" and the "Wesleyan & General." The former, on request, grants every year a health examination to whoever wishes it; the latter, biannually for sums of £500 and over. (The "Prudential" does not grant examinations, but helps those who have to be operated on, by granting them, free of interest, loans up to ninety guineas to every £1,000 for operations and nursing which, though not furthering early diagnosis, helps in the fight against disease.)

In Germany periodic health examinations began in 1925. At present there are seventeen companies that give their policy holders of sums varying between £150 to £500 (par) free health examinations triannually. Besides this, they are educating their public by means of illustrated journals, urging them to pay a timely visit to the doctor and to learn the early signs of disease, where this is important for a successful cure. They have created a popular film, "Don't Leave it to Chance," which promulgates the idea of the necessity of early diagnosis, and have organized a health service centre, the *Deutsche Zentrale für Gesundheitsdienst der Lebensversicherung*. In Switzerland the "Vita" has inaugurated such health service, and is offering it also in other countries (Belgium, Holland, Spain, France) where it has branches; the example has been followed by two more companies in Switzerland. In Austria the "Phoenix" does this kind of work; in Italy in great style, the *Istituto Nazionale delle Assicurazioni*; Japan also has made great progress in this line. In South Africa the "South African Liberal," and in Dutch India six companies, have taken up periodic health examinations, but only one company in Holland itself.

Those who are interested in the matter may find details in my article in the *Blätter des Roten Kreuzes* (February, 1928). It will be seen that there is room for improvement along these lines in regard to, and independently of, the question of life insurance. Dr. Roy Ward makes clear

the importance of drawing attention to the institution of periodic health examinations as such, which, as the insurance companies have recognized in the first instance, are one of the most important means not only of combating cancer, but in aiding preventive medicine. May I be allowed to associate myself with his views?—I am, etc.,

OTTO NEUSTÄTTER.

Scientific Director of the Deutsche
Zentrale für Gesundheitsdienst
der Lebensversicherung.

Berlin, Schlachtensee, May 29th.

The Method of Medical Care

SIR,—As one who may have earned the right to claim that he understands the difference "between sociology and socialism," may I express my congratulation upon your editorial in the *British Medical Journal* of April 7th, 1934? This clear and courageous statement will, I am sure, contribute to substantial progress in the United States.

Your editorial quite correctly recognizes that the anti-social stand of certain officers of the American Medical Association has latterly rested its case almost entirely upon the allegation that national health insurance in Great Britain has been a colossal failure, whether judged by public or by professional standards. The American medical profession has been almost persuaded that the British medical profession was opposed to national health insurance, or accepted it only on sufferance. If I may be permitted a colloquialism, your editorial, coming hard upon the heels of Sir Henry Brackenbury's article in the *New England Journal of Medicine*, and upon the publication of the report of the special commission of the Michigan State Medical Society, will "spike the guns" of this campaign of misrepresentation.—I am, etc.,

I. S. FALK,

Milbank Memorial Fund, Division of
40, Wall Street, New York, Public Health Activities.
May 16th.

Incidence of Cancer

SIR,—In a letter in your issue of May 26th (p. 963) your reviewer quotes from *Recent Advances in Pathology* figures the apparent meaning of which is that cancer of the lung has become much more common in recent years. He can only have seen the first edition of our book, since in the present one we also refer extensively to the statistical research of Professor Passey, whose conclusion is that the apparent increase in the incidence of lung cancer is due to improved methods and facilities for diagnosis. A striking fact which emerges from Professor Passey's analysis is that the increased incidence of the disease reported in this country is confined to hospitals at which there is a tuberculosis dispensary. In view of Professor Passey's findings we do not wish to be regarded and quoted as advocates of the belief that lung cancer is becoming more common, and we shall therefore be grateful if you will publish this qualification to your reviewer's statement.—We are, etc.,

May 31st.

G. HADFIELD.

LAWRENCE P. GARROD.

SIR,—May I do my best to answer Mr. Duncan Fitzwilliams's very pertinent question in the *Journal* of June 2nd (p. 1004)?

Although it is true that we have no reliable statistics of the extent to which primitive African or other civilized communities suffer from cancer, I doubt whether they would satisfy the statisticians even if we could obtain them. Differences in race, in colour, in evolutionary

position, in customs, etc., would introduce so many factors other than those due to civilization, or lack of civilization, that for the purpose of comparison they could hardly be so reliable as those which show the proportion of cancer suffered by the same civilized nation for a sufficiently long period of its history. And what could better answer the purpose than those statistics which have now been collected in our own country since the beginning of this century? During this generation the progress in material civilization has been so rapid that we should be well within the mark in estimating that it is equal to that made during the previous one hundred years. The figures are also not those of cancer in its early stages, such as might show a spurious increase due to improvements in diagnosis, but of cancers in their most pronounced forms, so pronounced, indeed, as to have caused death. The increase, moreover, is not a trifle, easily to be argued away, but is so considerable that it points to the conclusion that during the last thirty-three years of our intensive civilization cancer has almost doubled in frequency, in spite of the many thousands of lives which have been saved by better methods of treatment.

I fully agree with my reviewer that we ought not to blame civilization for this appalling increase in cancer, but some fault in our own particular brand of civilization. In the last century civilization brought with it a rising death rate from cholera, enteric fever, tuberculosis, and other diseases of insanitation. But these we now know were not directly due to civilization, but to faulty ways of living—to insanitation. And when civilization had advanced a little further, and the mistakes were corrected, the disorders due to them were either wiped out or are being wiped out.

After the same fashion it may reasonably be assumed that cancer is not a disease either of normal old age or of normal civilization, but of some error which now accompanies both of these conditions.

Doubtless I am running considerably in advance of my subject when I venture to predict that the fault of civilization which is to cancer what insanitation was to cholera and enteric fever, is abnormal degeneration. The Victorian oncologists were of the opinion that cancer is essentially a disease of degeneration, and I suppose this view is still held. But what the degenerating circumstances are, how they act, and in what way they can be prevented—or, in other words, how further civilization will enable us to get rid of them—can hardly be entered into here.

I must apologize to Mr. Duncan Fitzwilliams for the much too didactic turn which this reply to his letter has taken. My excuse is that it is his own fault, for it is provoked by the generous and kindly words in the opening sentences of his letter.—I am, etc.,

Reading, June 4th.

HASTINGS GILFORD.

Memorial to Dr. Haig Ferguson

SIR,—Some friends of the late Dr. Haig Ferguson feel that a proposal to have a permanent memorial to his life and work will meet with a ready and general acceptance—indeed, they believe, with an instant, glad, and even eager response, for it is not given to many men to hold the place Dr. Haig Ferguson won for himself by the force of his personality.

The chivalrous courtesy and unvarying kindness shown to everyone he had to deal with, in whatever rank or class they were, endeared him to the whole community. His skill in his own particular department of medicine, while making him the channel of incalculable benefit to his patients and their families, won for him the respect

and honour of the whole medical profession in Edinburgh and far beyond. And in another direction, less well known because of the essential modesty of the man, he has, as a wise and far-seeing philanthropist, influenced and helped many hundreds of needy girls at perhaps the most critical period of their lives. It is in this last characteristic that we see the possibility of founding such a memorial to Dr. Haig Ferguson as would be not only fitting and worthy, but would seem to be nearer to his heart than any other that could be projected.

For over forty years Dr. Haig Ferguson identified himself with the fortunes and work of the Lauriston Home—a home for unmarried mothers (first cases) where both pre-natal and post-natal care are provided, and where also, apart from those medical necessities, a refuge is afforded to those who are often in the extreme of misery, all the more intolerable in that it is mental rather than physical. The Lauriston Home is lineally descended from the St. Luke's Home which the late Sir John Halliday Croom founded some forty-five or fifty years ago. For the last thirty years at least Dr. Haig Ferguson was its moving spirit, and was in constant and intimate association with its work up to the time of his death. It may be said that of the many philanthropic activities with which his name was associated there was none which he had so completely at heart. The institution has a somewhat precarious existence, being entirely dependent upon the slender payments of the inmates, along with such subscriptions as a rather restricted circle of friends contribute; those last, being mainly due to the personal influence of Dr. Haig Ferguson, will now tend to cease.

If a sum of £5,000 could be raised the home could be placed on a lasting and permanent basis, and, as the "Haig Ferguson Memorial Home," would perpetuate the memory of a great and good man, while at the same time affording shelter to that class of unfortunate inarticulate people which was ever the object of his understanding and pitying solicitude. We commend this appeal to the personal and generous consideration of your readers in the belief that they will welcome the opportunity. Donations should be sent to R. H. Wallace Williamson, Esq., C.A., 37, Melville Street, Edinburgh.—We are, etc.,

R. W. JOHNSTONE,
Chairman.

A. E. LAURIE,
Vice-Chairman

ALISON RICHARDSON,
MURIEL A. NIMMO SMITH,
Joint Hon. Secretaries.

F. C. NIMMO SMITH,
Appeal Secretary.

Edinburgh, May 31st.

Strangulated Hernia

SIR,—Mr. Wood Power (May 26th, p. 964) pertinently asks in what percentage of cases I can carry out the injection treatment of hernia, and what are the percentages of cures and failures. Any oblique inguinal hernia that is completely reducible is suitable for this method of treatment. Size is no contraindication.

The results of cases where treatment has been completed are as follows: Total, 57—cured, 44; failures, 12; untraced, 1. This gives a percentage of cure of 77, but it must be taken into account that of my twelve failures four were direct hernias, and in one of these the bladder was incorporated in the neck of the sac; in two cases there were adhesions near the neck of the sac preventing complete reduction, as proved by subsequent events; one patient had had many previous operations, and his abdominal musculature was not good (however, he feels that his condition is considerably improved); in one case there was an enormous recurrence after an operation, and the neck of the sac was practically as wide as the

whole inguinal canal, so that it may be called direct. This accounts for eight of the failures. Of the remaining four, two received an insufficient number of injections—that is, the technique was faulty—and one of the other failures I strongly suspect has adhesions near the neck; the remaining patient wrote, in answer to my inquiry a short while ago, that he has had a recurrence on one side.

I therefore anticipate that by declining to treat cases of direct hernia, and those in which there is any suspicion whatever of adhesions near the neck, I shall effect a very considerable improvement in my percentage of cures in the future.—I am, etc.,

London, W.1, June 3rd. ST. GEORGE B. DELISLE GRAY.

Criticism of Ante-natal Work

SIR,—Though I am but a general practitioner I feel that the substance of the lecture entitled "A Criticism of Ante-natal Work" (May 19th) ought not to go uncriticized, for the impression which it leaves on one's mind is that it vastly overstates the dangers of induction, without due regard to its advantages.

In dealing with the question of induction, and of its safety or otherwise, surely one must take into consideration the stage at which it is performed. Though there can be no doubt that at the thirty-second week there must be danger to the child, I believe that induction at a fortnight, three weeks, or occasionally a month before term often makes all the difference between a long second stage with instrumental delivery and a reasonably safe normal labour. This I have done fairly often, and I think my figures support this statement, for it is common knowledge that the foetus is capable of growing disconcertingly during the last few weeks. Moreover, I have so far found that infants thus induced seem to progress as well as any others, at any rate while in hospital; and my opinion is that, provided the foetus "feels" a five- or six-pounder, there is little danger so far as prematurity is concerned.

I have under my care a small lying-in hospital where, during the last three years, we have had 777 cases—499 of which were primiparae and 278 multiparae. At this hospital I superintend and perform ante-natal work and any inductions I think fit, and in cases of difficulty during labour or the puerperium am called upon. Thus it is seen that there is continuity of treatment from start to finish. Of these 777 cases I have induced 127, twenty-nine of which had bougies inserted, the remainder having quinine; 109 were induced for "disproportion," post-maturity, or similar reason; ten for albuminuria; and eight for breech presentation.

This must seem an appalling proportion, but in these inductions there were only six stillbirths, of which five were probably due to causes other than induction. Two were forceps cases and one was post-mature; these made me wish I had induced earlier. One was a breech presentation with albuminuria, and yet another had albuminuria. There were, then, at the most, two in which induction could possibly be considered the causal factor. In only one of the bougie inductions was there any pyrexia, and that only the most transient. I feel that no criticism of the stillbirth rate in induction cases is fair unless it is compared with a parallel series of forceps cases, for surely one of the objects is to transform a potential instrumental labour into a normal one.

Of these 777 cases there were only twenty-seven forceps cases, which I am convinced is a lower rate than that which usually pertains, and I am sure that the high induction rate has saved many an instrumental labour. It is, moreover, instructive to see that among these twenty-seven forceps cases there were six stillbirths, and I feel sure that the dangers to the child are infinitely

greater from the use of forceps than from induction—let alone the dangers to the mother. In regard to breech presentations, should the foetus not be *persuaded* to turn, my policy is to observe its growth, and if in any doubt about the size of the head then to induce. This, I think, is better than the use of force under an anaesthetic. I must admit that compared with the lecturer's statistics my figures are small indeed, but they do represent one's personal work and experience, and I hope may be of some help in this difficult problem.—I am, etc.,

Manchester, May 25th.

C. VIBONT BROWN,
M.B., Ch.B.

Osteopathy

SIR,—Dr. Dorothy Wood's letter (June 2nd, p. 1009) greatly interested me. She describes understandingly the underlying pathology on which osteopathy is based. "Spinal displacements . . . are, in the main, static fixations of articulations which have been carried beyond the normal range of movement, and held in abnormal positions by the sustained unequal tension of ligaments, muscles, and surrounding soft tissues." Further on she states: "Owing to the highly cultivated tactile sense, which can only be developed by years of special training, the osteopath is able to detect these fine deviations from the normal, vertebral or otherwise, which are usually not apparent to the surgeon."

It is her assertion of this very highly developed technique of spinal manipulation, only possessed by the initiated, which arrested by attention, for not long ago one of my patients was treated by an osteopath for twenty weeks, and as I was anxious to know what the treatment consisted of I questioned and cross-questioned the lady at some length. One of course does not always believe the stories of patients, but in this particular case I believe the story to be true. The osteopath she consulted was the genuine article from the Middle West—not a mere native imitator of occidental healing.

The procedure was as follows. The patient stripped to the waist in an ante-room, and then was ushered into the presence of the osteopath, who "rubbed" her spine for about a quarter of an hour (of course this "rubbing"—the patient's own words—may be the manipulation of the spine by the highly cultivated tactile sense of the osteopath). After the "rubbing" was over she was sent into another room, still stripped, and was exposed for another fifteen minutes to the rays of a violet lamp. She then dressed, deposited her guinea, and left, to return week by week. As she did not seem to make much progress the osteopath applied tonsil suction (evidently the osteopath was trying to see if draining the tonsils would produce more effective results).

Her friends who had recommended the osteopath inquired as to her progress. She replied that she was no better. "Wait until he gets on your back," was their assurance. At the next visit he got on her back. She lay on a couch face downwards, and the osteopath got astride of the patient and pressed firmly with both hands on the lumbar vertebrae, causing considerable pain. After this experience of the "highly cultivated tactile sense" she did not return. She is still alive and well—an osteopathic cure!—I am, etc.,

Warrington, June 3rd.

J. S. MANSON.

SIR,—Dr. Dorothy Wood, in her reply to Mr. Bankart's article on osteopathy, makes some alarming statements. In regard to the spinal "displacements" to which she refers, may I ask her why these cannot be demonstrated radiologically? How does she defend the common practice of a patient attending an osteopath regularly once a week

to have a "bone put back in the spine"? Such patients abound at orthopaedic hospitals—after they have been relieved of their money, but not of their disability. If Dr. Wood wishes, I can easily give her ample proof of the above statement.

Allow me to mention just three cases I have seen during the last few days which disprove Dr. Wood's contention that osteopathic principles are based on sound pathology.

1. Internal derangement of the knee-joint. "Bone put back" by osteopath, who advised the patient that he must "avoid getting water on the knee." Result—the knee-joint again became deranged on the homeward journey. Osteopath refused to see him.

2. Typical chronic tenosynovitis of the flexor tendons of wrist. "Bone put back," with no relief of symptoms.

3. Tuberculous shoulder-joint, with cold abscess on the arm. Manipulated by osteopath.

As regards the so-called "highly cultivated tactile sense" which osteopaths possess and surgeons do not, this is surely a doubtful advantage when it leads them so often to find displacements which are not present and to overlook such diseases as tuberculosis and cancer which are.—I am, etc.,

Hove, Sussex, June 4th.

J. M. TURNER, F.R.C.S.

The Medical Charities

SIR,—I hope that Dr. Arnold Gregory's letter (May 26th, p. 962) on the matter of the medical charities will be read by all members of the Association; it sums up the present situation, and gives some indication as to what is required to improve the state of affairs.

A letter such as Dr. Gregory's should be quite unnecessary; special charity weeks should be unnecessary; all the usual methods we now employ to gather together a few pounds for the charities should be unnecessary. It should be the wish and duty of every man and woman in the profession to impose a tax on his own earnings so that he may subscribe towards the relief of his colleagues or his late colleagues' dependants. There must be very few practising men who cannot afford to make at least one donation to the funds of the charities; many of these could well afford a small annual subscription. I feel that we should now aim at making a levy on the members of the profession in order to raise the capital sum mentioned by Dr. Gregory: 50,000 practitioners of medicine ought to be able to give one guinea each towards this sum. In addition, a similar sum ought to be raised every year by annual subscription. A levy and compulsory subscription should cause no hardship at all, and would render quite unnecessary all the special functions and all the campaigns of the various organizations at present in the field (all clamouring for subscriptions, all overlapping in their appeals, all quite inadequately supported).

The experience of charities secretaries in most Divisions is that letter and personal canvass will produce nothing further; the average medical man seems to be somewhat apathetic and unconcerned when the matter of charities crops up. More than once I have been told by a practitioner that no man ought to be "so down and out" that he cannot make provision for his family; but because he himself is "too hard up" I have not succeeded in extracting a subscription. However, until the ideal can be attained, we must make special efforts on the lines suggested by Dr. Gregory. I would suggest that the first move should be towards reconstitution of the Central Charities Committee of the Association. There ought to be more direct representation of the Divisional charities secretaries (who are the fellows who do the donkey-work): this committee should co-opt representa-

tives from all the charities, and also any hard-working men and women whose services may be useful. The next step should be the organization, by the committee, of a conference of all B.M.A. charities secretaries, local Royal Medical Benevolent Fund secretaries, Epsom College local secretaries, Ladies' Guild secretaries, and so on. At this conference the whole matter of medical benevolence could be reviewed, a committee formed to draw up a new scheme, and a general stimulus given to the profession to look to its dependants.

I would suggest that as the Annual Meeting of the B.M.A. will not be held in England in 1935 it would be very convenient to have the first conference of charities secretaries next year. If the conference is to do any good work it must be unhampered by other business: we want no more fiascos like that at the Eastbourne Meeting in 1931.—I am, etc.,

RAYMOND H. ROBINSON,
Charities Secretary, Torquay Division, B.M.A. ;
Local Secretary, Epsom College.

Torquay, May 28th.

Scottish Medical Golfing Society

SIR,—Will you kindly grant us space in your columns to announce the birth of the Scottish Medical Golfing Society. On April 20th, 1934, a meeting was held at the Langham Hotel for the purpose of giving concrete form to a common desire that Scottish members of the medical profession in the London area should meet occasionally throughout each year for the express purpose of vying with one another in propelling the golf ball from tee to hole, according to the rules of golf. The various offices were created, and the following were filled:

President.—Bertram Shires.
Vice-Presidents.—Sir Ashley Mackintosh (Aberdeen), Sir Robert Muir (Glasgow), Professor Musgrove (St. Andrews), and Sir Harold Stiles (Edinburgh).
Honorary Treasurer.—Bruce Williamson.
Honorary Secretaries.—Norman Fleming and Burton Yule.
Councillors.—A. Landale Clark, A. K. Forbes, D. McKenzie, D. J. MacMyn, J. W. Skelley, and L. E. Barrington Ward.

An entrance fee of one guinea and an annual subscription of one guinea will be due from all members of the society, the subscription being paid by a standing banker's order so long as membership of the society is held. Doctors who are interested are requested to apply for membership to the undersigned, stating their qualifications for the above society, also club and handicap.—I am, etc.,

92, Harley Street, W.1, June 2nd. NORMAN FLEMING.

Poisoning by Ground Ivy

SIR.—The plant I referred to is the "ground ivy" of all our herbals and botany books going back to the middle of the sixteenth century. It is a labiate and not a *Hedera*. The ordinary *Hedera* climbing ivy often has a creeping ground habit. In some respects it is a remarkable plant. When grown on a tall wall the upper part takes on quite a different appearance from that of the lower. The late Harrison Weir, the artist, showed me a stout-looking shrub in his garden. When I asked him what it was, he replied, "Ivy off the wall." He had cut down the upper three or four feet from the main stem and planted it. It took, and grew into a big bush. Common "wall" ivy is not poisonous, as sheep will eat it freely, and walls when covered by the plant have to be fenced to keep them off. I have made inquiries as to what "ground" ivy contains in a pharmaceutical way. Beyond an aromatic oil of no great strength, the answer is "Practically nothing." I wonder if the infusion contains a sufficiency of gum to protect the skin

from the air or the clothing, or whether the gum plus the oil gives the relief. At any rate, the infusion works, and as a help in these miserable cases of prurigo it is worth a trial. I used the fresh plant, but a herbalist, writing to me, indicates that the dried plant is also useful. This is the best time to gather it—when in bloom and full of juice.—I am, etc.,

Appledore, Kent, June 3rd.

F. WILLIAM COCK.

Tests for Drunkenness

SIR,—After all these years of doubt it is indeed a relief to find that medical men, especially police surgeons, have had removed from their minds, by a recent decision, the anxiety invariably caused by a police call to a case of "Drunk in charge of a car." I admit it has taken much time and thought to arrive at a satisfactory conclusion. Cases are apparently now divided into two groups: (1) the one in which the person implicated declines to be examined, and, the act of forcible examination being a trespass vetoing any test, the solicitor is in the happy position of demanding an acquittal on the ground that no tests were employed; (2) the other in which the fact that the implicated person asked for an examination is to be accepted as a clear proof that he is sober. All most satisfactory to the accused and to the medical man.—I am, etc.,

June 4th.

J.P. POLICE SURGEON.

Obituary

E. E. BOWDEN, M.R.C.S., L.S.A.
Consulting Surgeon, Warrington Infirmary

On Sunday, June 3rd, Warrington lost her oldest practitioner by the death of Dr. E. E. Bowden. He had been in poor health since last autumn, and was confined to bed for the last five months. He was born at Patricroft, near Manchester, on September 9th, 1862, and had been associated with Warrington for forty-seven years. He was appointed junior house-surgeon at the Warrington Infirmary immediately after qualifying as M.R.C.S. and L.S.A. in 1887, and continued in residence there as senior for nine years. He commenced in general practice at Warrington in 1896, and held numerous appointments: Post Office, factory surgeon, medical officer to the Training College until its removal to Liverpool, police surgeon, and surgeon to the Warrington Infirmary for twenty-five years, retiring in 1922, when he was presented with a testimonial from the board of management. During the war he was chairman of the Recruiting Medical Board, and acting D.C.M.S. of the Ministry of National Service and Ministry of Pensions. He was also medical referee for the Warrington, Leigh, Altrincham, and Wilmslow county courts.

Dr. Bowden joined the British Medical Association in 1888. He was a member of the Manchester Pathological Society, the Royal Institute of Public Health, and the Society of Members of the Royal College of Surgeons. He was chairman and secretary of the old Warrington Medico-Ethical Society, now defunct. He was the first chairman of the Warrington Panel Committee, and also chairman of the Warrington Division of the British Medical Association, to which he was always loyal. This record shows that he had a variety of interests associated with the practice of medicine, and all his work was accurate, painstaking, and thorough, and much appreciated by the higher authorities whom he served. Behind a stern and somewhat brusque manner he hid a kindly and sympathetic heart, and his familiar figure will long be missed.

JUNE 9, 1934]

in the homes and numerous factories and workshops of Warrington. He leaves a widow and two sons, one of whom is a member of the medical profession.

J. S. M.

THE LATE DR. WILLIAM B. PATERSON

Sir James Barr writes: I am very sorry to learn of the death of Dr. W. B. Paterson from the excellent obituary notice by Dr. Robert Coope in the *Journal* of June 2nd. I owed many obligations, professional and personal, to Dr. Paterson, whom I always held in the highest esteem, and patients might trust their lives with confidence to him. I have a lively recollection of one night when getting off a tram-car the driver failed to stop and my right humerus was dragged out of its socket. I was assisted home. A surgical colleague was telephoned for, but he was at an operation and could not come for at least half an hour. A practitioner friend was obtained, but he had no anaesthetic. He laid me on the floor, and with his foot in my axilla he pulled for a considerable time, but, contrary to my expressed wish, he gave up the job as hopeless and sent home for chloroform. I told my wife that I could not lie in agony till his return and asked her to ring up Paterson and tell him to bring chloroform with him. He arrived almost immediately fully armed and I asked him to put me under chloroform and keep me deeply under till the dislocation was reduced. I woke up comfortably in bed. The following day the surgeon and my other friends insisted on giving me a dose of tetanus antitoxin. My recovery from the accident took about six months. I very much regret that I did not hear of Paterson's illness when I was in Liverpool about nine months ago. The medical mortality in Liverpool of late has been somewhat appalling, and I am now very sorry to find Paterson added to the list. I wish to extend my sincere sympathy to Mrs. Paterson.

Dr. JOHN MYLES of Dolgelley was born in Limerick in 1855, and received his medical education at Trinity College, Dublin. Before this he had spent many years in Australia and New Zealand, and served in the New Zealand Artillery in the second Maori War. He graduated M.B., B.Ch. Dublin in 1889, and obtained the F.R.C.S.I. in the same year. In 1894 he proceeded M.D. After graduation he returned to New Zealand, engaged in private practice at Kumara, and was appointed medical superintendent of the Ross and Kumara hospitals. Five years later he came to England, living in Clapham, eventually removing to Dolgelley, where he had practised for twenty-seven years. At the outbreak of the Great War, although over military age, he obtained a commission as Captain R.A.M.C., and was medical officer to the Caernarvon Auxiliary War Hospital. Dr. Myles took an active part in the formation of the Dolgelley branch of the British Legion, and in recognition of his services in this connexion was awarded the gold badge of the Legion. He had been a member of the British Medical Association since 1897. A great athlete in his youth—he was an Irish Rugby international in 1875, and at about the same time was in the crew at Henley which won the Ladies' Plate—he carried with him through his life a zest for active pursuits and a great love for his fellow men. Wide in his reading as in his travels, he was a man of broad outlook, and a welcome member of many social organizations. His geniality and exceptional talent for making friends endeared him to his colleagues and patients, and at his funeral Dolgelley Parish Church was crowded with representatives of the many interests he had espoused in a long life of devoted service.

The following well-known foreign medical men have recently died: Dr. CHRISTIAN ZOELLER, professor of epidemiology and bacteriology at the Val-de-Grâce School of Medicine, Paris, aged 46; Dr. CHEDA MIHAILOVITCH, formerly Minister of Health at Belgrade, aged 64, from anthrax; and Professor ARTHUR HÜBNER, director of the Nerve Clinic at Bonn, aged 55.

Medico-Legal

BUSINESS RELATIONS BETWEEN DOCTORS

This is the first of a series of articles, contributed by a legal correspondent, on some practical aspects of business transactions between medical practitioners.

GENERAL CONSIDERATIONS

When a doctor buys or sells a practice, or takes a partner, an assistant, or a locumtenent, or enters the employment of another as an assistant or locumtenent, he creates, whether he realizes it or not, a legal relationship which is bound by legal rules. Unfortunately, the experience of the large defence societies, of the British Medical Association, and of those solicitors and agents who are accustomed to these transactions shows that doctors are lamentably careless in their dealings with one another. Men who take the most scrupulous care of their patients may display in their business relationships an indifference which if carried into their professional life would quickly expose them to a charge of manslaughter. The reason for this widespread failing may be a large generosity of mind, which assumes that other persons are honest and will carry out their intentions and obligations loyally, and which cannot see the necessity for legal compulsion. It may be a preoccupation with the needs of sick bodies and minds, and an impatience with intellectual abstractions which seem to have no practical value. But the fact remains that solicitors who specialize in medico-legal work are constantly being called in to unravel the complicated and acrimonious problems that arise when two or more medical men, in addition possibly to a number of lay relatives, have involved themselves in a financial and professional relationship of vital importance to all concerned, have based years of their working lives and hundreds of pounds of their savings on it, and then, when the situation is transformed by a quarrel or a death, find that their intentions have never been clearly stated and agreed, and that they all hold completely different and antagonistic views about the rights and duties of each party to the arrangement.

The purpose of this paper is therefore twofold: to persuade the medical practitioner how important it is to conduct his business relationships with his fellows in the proper legal way, and to show him something of the law governing these relationships. It is impossible to avoid giving a certain amount of general advice as distinguished from legal information, but this tendency has been resisted as far as has been practicable. The material is not by any means original. For practically all of it the author is indebted to the classical textbook of Barnard and Stocker, the earlier chapters of *The Conduct of Medical Practice*, various articles and letters that have appeared from time to time in the *British Medical Journal* and the *Lancet*, and the more recent annual reports of the two great professional defence societies.

The chief business relationships between doctors are those of partnership, of a principal with his assistant or locumtenent, and of a doctor selling his practice with the doctor who buys it. These relationships have several features in common. He who buys part of a practice is at once a purchaser and a prospective partner, so his relationship with the vendor—the technical term for a party who is selling something—is a double one. A doctor sometimes becomes an assistant with a view to becoming a partner later on; or under terms, such as a small share in the profits in addition to his salary, which make his position difficult to distinguish from that of a partner. A locumtenent's position is much like that of an assistant, but as it is transitory it does not involve much provision for the future.

INTANGIBLE ASSETS

Business relationships between doctors, and indeed between other professional persons, have one notable feature which distinguishes them from those between commercial or financial persons. A commercial or financial business usually involves a good deal of tangible property, such as land, buildings, or money. A medical practice rarely has any property attached to it, but consists almost entirely of the intangible factor known as goodwill—that is, the readiness of patients to consult the owner of the practice. The value of a practice is the value of its goodwill, an important ingredient of which is the number of patients and the size of the fees they pay. For this reason a doctor who buys a practice or a share in one can never know, despite the most skilled and careful investigation, quite what he is getting. The purchase price is calculated on the gross receipts, but the real value of the practice will depend to an overwhelming extent on subtle factors like the completeness of the introduction, the willingness of patients to transfer to a stranger, and the extent to which they like the new-comer personally. Similarly, the value of a share will depend largely on the manner in which the established partner behaves after the agreement is signed and joint work is started: whether he is loyal or obstructive; whether he works or slacks. A former owner or assistant who sets up practice in the neighbourhood may draw off a large number of the patients and reduce the value of the goodwill disastrously.

The only tangible property included in the practice will, as a rule, be a few medical stores and some stationery, for if a house or surgery goes with the practice it is usually much more convenient to transfer the legal interest in it by a separate transaction with separate documents. A new practice is therefore as intangible and abstract a chattel as it is possible to buy, sell, or share. It is practically true to say that the purchaser takes, and the vendor sells, a potential interest in a number of psychological complexes belonging to various persons domiciled in the neighbourhood who are not concerned in the contract. The essentially abstract nature of a practice, considered as a valuable thing, dominates all business transactions connected with it. The one question that is ever present may be put thus: "What effect is this change, this conduct, going to have upon the feelings of the patients?"

The law, though no stranger to the concept of goodwill, is not very closely adapted to business relationships between medical men. It is chiefly framed for commercial partnerships and agency and the transfer of tangible property, and its concepts are sometimes difficult to apply to professional transactions. For instance, when a partner dies, his executors cannot claim anything for his estate in respect of his share of the goodwill. It is not legally a partnership asset for purposes of valuation, although the firm may own nothing else. It is practically impossible to confine within legally intelligible propositions the subtle mental factors which are so vitally important in medical relationships. The capacity of the law and legal agreements to control these transactions is much less than in commercial relationships, and their success depends far more on the personal and professional integrity of the parties.

IMPORTANCE OF A LEGAL AGREEMENT

Nevertheless, the fact that the scope of the law is especially limited in medical relationships does not make the law any less important within that scope, but rather more. Medical men are always tempted, and very often succumb to the temptation, to say: "We are both men of honour and know what we want; why should we bind ourselves with a legal agreement? Surely we can each trust the other to do his duty without this compulsion. Why should we pay a lawyer a fee to type out in complicated language what we can express simply?" Some doctors put nothing in writing at all; a few others, with

more sense, put their bargain in writing and exchange signed copies. Both groups, however, are risking grave trouble, for many reasons. The first and most obvious risk is that one or both will turn out deliberately dishonest. The second is that, with the best intentions in the world, they will disagree on what they really meant. If the bargain has never been put into writing, this development is not only probable but almost certain. Even if the terms have been written down, there is ample room for difference on their interpretation.

The third risk is that one of the parties will die and that his personal representatives, inquiring into his interest in the practice, will find absolutely no record of its limitations. When a disagreement of this kind develops there is often nothing to be done but to call in a lawyer with experience in medical relationships to sort it out. Contracts for the transfer of a practice for partnership or for assistantship are valid even though they are not expressed in writing. A contract exists, but its terms can only be deduced from the conflicting evidence of the parties, one of whom may be dead, and of persons who may have been in close enough contact with them to know what they intended; and from the behaviour of the parties—the way in which they carried on the business. Even when the parties are friendly and anxious to reach a settlement, this process is tedious and unsatisfactory; when they are hostile it may involve a lawsuit in the Chancery Division costing hundreds of pounds. In any event the whole trouble could have been avoided altogether by consulting an experienced solicitor before entering into the relationship and having the bargain expressed in proper legal form, which, whatever the contracting parties may forget or misunderstand afterwards, will always convey a definite and unequivocal meaning to a lawyer.

The following is a typical example, reported by a defence society, of the evil consequences of neglecting to have a legal agreement drawn up.

Two doctors fell out over an agreement to transfer a practice on the Continent. The question at issue was whether a definite contract had been made. As both parties had approved the terms but the agreement had not been signed, various legal difficulties were introduced. Fortunately both were members of the same defence society, and the dispute was settled by the society's solicitors, but the practitioners would have saved themselves and their society much trouble if they had employed the solicitors to keep them from making a muddle instead of to get them out of it.

Moreover, this work should always be entrusted to a firm with special medical experience. With great respect to the members of an admirable and indispensable profession, not all, and probably not many, solicitors are so familiar with medical practice and partnership as to be able to draw up an agreement which will avoid the many traps which lie open to the stranger.

In the annual report of the Paddington Houses Association Ltd. it is stated that during last winter cooking demonstrations were arranged for the tenants of houses belonging to that body. These were based to some extent on the report of the British Medical Association on the necessary minimum weekly expenditure on food per family, and weekly menus were drawn up in accordance with it. It was found that this standard of nutrition was above what could be afforded by many in one of the areas. The material for use in these classes was obtained from local shops. Emphasis is laid on the economies resulting from the wise use of gas in cookery and the planning of meals days ahead, as well as on the value of milk and cheese for children. The Paddington Houses Association now owns eighty-five houses, all free of mortgages. It houses 322 families, comprising about 1,365 persons. Owing to shortage of cheap accommodation in the vicinity it is still compelled to allow a larger number of persons per room than is desirable. Close co-operation is maintained with the borough council in its work against overcrowding.

JUNE 9, 1934]

Universities and Colleges

UNIVERSITY OF OXFORD

A congregation held on June 2nd the degree of Doctor of Medicine (D.M.) was conferred on K. N. Irvine.

UNIVERSITY OF LONDON

Dr. G. R. Cameron and Dr. L. P. Garrod have been assigned to the Faculty of Medicine.

Mr. N. J. Ainsworth, M.R.C.S., L.D.S., has been recognized as a teacher of dental surgery at the Royal Dental Hospital of London, School of Dental Surgery, and assigned to the Faculty of Medicine.

Professor H. S. Raper, D.Sc., M.B., F.R.S., has been appointed as an additional external examiner on the Board of Examiners for the Diploma in Biology in 1934.

The Regulations for the Academic Post-Graduate Diploma in Medical Radiology (*Red Book*, 1933-4) have been amended as follows: (1) By the addition of the following after the seventh paragraph on page 497:

"Students who have passed the B.Sc. (Special) Examination in Physics as Internal Students of this University will be exempted from the course of study and examination for Part I of the Diploma."

"Students who have passed the B.Sc. (General) Examination in Physics or the B.Sc. (Special) Examination with Physics as their subsidiary subject as Internal Students of this University will be exempted from the course of study for Part I of the Diploma."

(2) By the deletion of the tenth, eleventh, and thirteenth paragraphs on pages 497-8 and the substitution thereof of the following:

"Part I of the Examination will be held twice in each year, beginning on the Tuesday following the third Monday in March and on the first Monday in December."

"Part II of the Examination will be held twice in each year, beginning on the third Monday in June and on the second Monday in December."

"Every student entering for either or both parts of the Examination must apply to the Academic Registrar for an entry form and a certificate of course of study, which must be returned duly filled in and attested in accordance with the General Regulations as to Approved Courses of Study, together with the proper fee, not later than February 8th for the March Examination, April 8th for the June Examination, or November 8th for the December Examination."

The following appointments have been made: Professor G. E. Gask, F.R.C.S., and Mr. H. L. Eason, M.S., F.R.C.S., as Governors of the British Post-Graduate Medical School; Sir Cooper Perry, M.D., as representative on the governing bodies of the National Training College of Domestic Subjects and the Battersea Polytechnic; and Dr. H. G. Cook, F.R.C.S. (nominated), to act as representative on the Court of Governors of the University College of South Wales and Monmouthshire for a further period of five years as from October.

Applications for the William Julius Mickle Fellowship must be sent in by October 1st. The Fellowship is of the value of at least £200, and is awarded annually by the Senate to the man or woman who, being resident in London and a graduate of the University, has in its opinion done most to advance medical art or science within the preceding five years, and has therein shown conspicuous merit. Further particulars may be obtained on application to the Academic Registrar.

Provided there is a candidate of sufficient merit, a Paul Philip Reitlinger Prize of £30 will be awarded on December 3rd for the best essay embodying the result of some research work on a medical subject carried out by the candidates, who must be matriculated students who, on June 1st preceding the award, were studying in one of the schools of the University in the Faculty of Medicine, or graduates of the University who on the same date were of not more than five years' standing from the taking of the first degree, and are or were students of such school. Essays must reach the University by October 1st and regulations for the award of the prize may be obtained from the Academic Registrar.

UNIVERSITY OF WALES

The following candidates have satisfied the examiners in the examination indicated:

TRIPLE FIRST DIVISION.—P. K. Ghosh, B. K. Pal, H. K. B. Resteg, P. K. Sen, H. A. Zali.

SOCIETY OF APOTHECARIES OF LONDON

The following candidate has been approved at the examination indicated:

MAJOR OF MIDWIFERY.—Marjorie Houghton James, M.B., B.S., D.P.H.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

At the monthly meeting held on June 1st a resolution was adopted in silence expressing regret at the death of Dr. John Hugh Robert Glenn, a Fellow of the College.

The following were admitted Licentiates and Members of the College: W. R. F. Collis, M. J. O'Donnell, R. B. Pringle, and T. F. M. Woods.

The Services

DEPUTY DIRECTOR-GENERAL, A.M.S.

The War Office announces that Colonel W. P. MacArthur, D.S.O., O.B.E., M.D., F.R.C.P.I., Honorary Physician to the King, who is at present consulting physician to the Army and professor of tropical medicine at the Royal Army Medical College, has been appointed Deputy Director-General, Army Medical Services, the War Office, with effect from September 16th, in succession to Colonel F. D. G. Howell, D.S.O., M.C., Honorary Surgeon to the King, who, on completion of his temporary tenure of the appointment, will proceed to India to take up the appointment of Deputy Director of Medical Services at Army Headquarters, which will become vacant on December 26th. Colonel MacArthur will be succeeded as consulting physician to the Army and professor of tropical medicine at the Royal Army Medical College by Lieut.-Colonel J. Heatly-Spencer, O.B.E., M.D., R.A.M.C.

LEISHMAN PRIZE

Major F. McKibbin, R.A.M.C., has been awarded the Leishman Prize for the year 1933, consisting of a silver medal and a sum of £30, for his work in the interests of military hygiene. This prize is awarded annually for the best piece of work in any branch of medicine, surgery, or allied sciences, or in connexion with the general duties of the Royal Army Medical Corps, by an officer of the R.A.M.C. or Army Dental Corps, or by an officer removed from either of these corps but still on the active list.

NORTH PERSIAN FORCES MEMORIAL MEDAL

Surgeon Lieutenant-Commander S. G. Rainsford, Royal Navy, has been awarded the North Persian Forces Memorial Medal for the year 1933 for his paper on "Laboratory Methods of Diagnosis of Brucella Infections" published in the *Journal of the Royal Naval Medical Service*, January, 1933. This is awarded annually for the best paper on tropical medicine or hygiene published in any journal during the preceding twelve months by a medical officer, of under twelve years' service, of the Royal Navy, Royal Army Medical Corps, Royal Air Force, Indian Medical Service, or of the Colonial Medical Service, provided the Memorial Committee considers that any of the papers published has attained a standard of merit justifying an award.

DEATHS IN THE SERVICES

Colonel Robert Blood, late R.A.M.C., of Kingstown, County Dublin, died on April 2nd, aged 57. He was born on March 10th, 1847, was educated at Queen's College, Galway, and in the school of the Royal Irish College of Surgeons, Dublin, and graduated M.D. and M.Ch. in the long-defunct Queen's University of Ireland in 1871. Entering the Army as assistant surgeon on September 30th, 1871, he became colonel on August 10th, 1901, and retired on August 13th, 1904. In the old regimental days he served in the King's Regiment, the 8th Foot, now the King's Liverpool Regiment.

Surgeon Captain John Joseph Hogan Rooney, R.N. (ret.), died after a long illness in the Royal Naval Hospital, Chatham, on May 24th. He was educated at the Cecilia Street Hospital, Dublin, and in the school of the Royal College of Surgeons, Edinburgh, and took the Scottish triple qualification in 1901, after which he entered the Navy as surgeon. He attained the rank of surgeon commander on January 1st, 1917, and retired with an honorary step of rank as surgeon captain on August 18th, 1925. He served in the war of 1914-18, receiving the medals. He leaves a widow.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

The House of Commons spent two days this week in committee on the Finance Bill. Post Office Estimates, import duties on iron and steel, and the second reading of the Milk Bill were down for other days. On June 5th Mr. Chamberlain announced that no instalment would be paid to the United States in respect of War Debt, pending discussion. Statements on nutrition were made at meetings of private members' groups in the Commons.

On May 30th the House of Lords agreed to amendments made by the House of Commons to the Birmingham United Hospitals Bill.

The Statutory Salaries (Restoration) Bill was read a first time by the Commons on May 30th.

The Licensing (Permitted Hours) Bill, "to make provision with regard to the power to make, and the validity of, directions as respects a part of the year only, and to the power to fix, and the validity of decisions fixing, the permitted hours on weekdays where such decisions are so made," was introduced in the Commons by Sir John Gilmour on May 30th, and read a second time on June 1st.

The Protection of Animals (Cruelty to Dogs) Scotland Bill passed through Committee in the House of Commons on June 4th without amendment, and was read a third time. It was read a first time by the House of Lords on June 5th.

In the House of Lords on June 5th the Unemployment Bill was discussed on the motion for the second reading. Lord Marley, in criticizing the Bill, cited medical evidence as to malnutrition among children of the unemployed. The debate was adjourned.

Health of School Children

Debate on Education Estimates

In committee of the House of Commons, on May 30th, Mr. RAMSBOTHAM introduced the Board of Education Estimates for 1934. The total was £42,104,018. He estimated that during the year the Exchequer and the rates between them would find about £82,000,000 for education. Reports received did not confirm the impression that the physical condition of the children was deteriorating in consequence of prolonged economic distress. The school medical officer for the North Riding of Yorks reported that out of 13,000 children medically examined only seven were really bad cases. The percentage of children pronounced subnormally nourished declined from 6.54 per 1,000 in 1930 to 3.97 in 1933. The school medical officer for Thornaby and Eston said that about 50 per cent. of the men there were unemployed, but an amazingly high standard of nutrition was maintained. The few that were underfed did not suffer from lack of quantity but of quality of food, and this not because of poverty. Mr. Ramsbotham added that certain cases of malnutrition arose not on account of poverty but of organic defects and delicacy. A recent investigation found that it was comparatively rare for the brothers and sisters of a malnourished child to show any signs of malnutrition. In the country as a whole the number of malnourished school children per 1,000 was 11.2 in 1931, 10.7 in 1932, and 11.1 in 1933. This year 190 out of 316 authorities had exercised powers under the school-feeding sections of the Education Act, and ten more were expected shortly to do so. The authorities covered about 70 per cent. of the school population of England and Wales. Over 90 per cent. of the children in industrial areas were covered by authorities which exercised these powers. In seaside towns, small country towns, and rural areas the problem of malnutrition was small or negligible. The Board of Education paid a grant at the rate of 50 per cent. on the provision of meals. In 1928 the net expenditure of the authorities in this service was £227,000; last year it was £560,000. In February,

1934, the authorities fed 292,000 children, either with ordinary meals or with milk, 212,000 of these being fed free of charge. Although only 1 per cent. of the public elementary school children were reported to be suffering from malnutrition, free meals and milk were provided for over 4 per cent. In addition, about 900,000 children received one-third of a pint of milk daily for a penny under voluntary schemes organized by the National Milk Publicity Council. To say that all poor children, irrespective of physical condition, should be fed at the expense of educational funds was a suggestion he could not accept. Provision of meals should be based upon a selection by school medical officers, supplemented by reports from their teachers, the children included being those who showed any signs of subnormal nutrition. Experience in the most distressed areas showed it possible to keep malnutrition in check by providing dinners, or even milk only, under a system of medical selection, not including those children who, though poor, were able to take advantage of the education offered them. No embargo had been or would be placed on the school medical service. Last year the Board approved seventeen proposals for new clinics and 124 forms of inspection and treatment, and this year the Estimates allowed for an increase in the cost of the school medical service. The Board intended to press on the reorganization of the schools on the lines of the Hadow report. Every type of child, whether clever or backward, benefited in the senior schools set up under that report.

Malnutrition in Distressed Areas

Mr. COVE moved a reduction in the Estimates. He contended that an embargo was maintained against the provision and improvement of school buildings. A spokesman of the Association of Education Committees had asserted that, in general, new proposals for the amelioration of the conditions of very young, ailing, and defective children, and for the extended provision of playing fields, were rejected by the Board. Approval was not generally given to the provision of nursery schools, open-air schools, or schools for defective children. Mr. Cove inquired whether the circular issued in September, 1931, restricting developments in the education service, had been scrapped. A feeling was growing up that the reports upon the nutrition of school children were not as objective as they might be. Everyone connected with the distressed areas knew children were ill fed and ill nourished. Doctors themselves did not know what malnutrition was technically, and did not accept any universal test. An investigation had lately been made into the physical condition of children under 5 in Newcastle. Nearly half the children in the poorer class were found to be below the standard height, compared with 5 per cent. of the better-class children. In weight more than half the children of the poorer class were below the standard, as against 13 per cent. of the better-class children. Only 2 per cent. of the poorer children were above the standard, compared with 25 per cent. of the better-class children. Only 20 per cent. of the poorer children passed an anaemia test satisfactorily, and 23 per cent. were found to be definitely anaemic. Of 125 poorer children forty-nine had suffered from acute or chronic chest trouble, compared with only five of the 124 better-class children. This investigation established the need for improved attention to the physical well-being of children from the ages of 1 to 5. Sir PERCY HARRIS pointed out that the House was debating the Education Estimates without the annual report from the Board or that from the Chief Medical Officer. The latter was always one of the most remarkable documents published by the Stationery Office. When the history of public health in this country was written, Sir George Newman would be shown to have contributed more to it than any other medical man or public officer. Was the Board meeting the criticisms of its own medical officer and adviser? In the light of his advice, would Mr. Ramsbotham make a statement on nursery schools, and give a lead to the country?

Vocational Tests

Dr. G. MORRISON, speaking as an old head master, said British methods of vocational testing had been rough-and-ready. He had seen in an elementary school in Rome a complete psychological laboratory to serve that school and

three or four others. In charge of it were two trained psychologists, one with a medical degree, and it had delicate, expensive, and elaborate machines for testing response to stimuli and so on. Though this was mainly for the benefit of those leaving school, the testing was done throughout the school course, and accurate records were kept. He asked Mr. Ramsbotham to consider the possibility of doing something in that direction, and more scientifically than in the past. Mr. WEST said that Mr. Ramsbotham would find in Kensington, if he investigated in conjunction with the medical officer of health, an abnormal number of cases of malnutrition. In the northern division of the borough he would find a disease rate in children double that in the southern part, and an infantile mortality of 120 per 1,000. Mr. ERNEST EVANS suggested that the Board of Education should consult the Ministry of Health about improving the water supplies to schools in rural areas.

Need for More Nursery Schools

Lady ASTOR said that of children up to 2 years only 50 per cent. got the benefit of infant welfare services. Between the ages of 2 and 5 there was a gap in the treatment of children. Of those entering the schools at 5 between 40 and 50 per cent. showed signs of rickets, while 27 per cent. were physically impaired. In 1932, in every 1,000 children between 5 and 15, 194 required treatment, 174 medical observation, and 613 dental treatment. Nearly 58,000 children were in special schools for the blind, deaf, tuberculous, epileptic, mentally deficient, or crippled. Nursery schools were a necessity, and the "cuts" on them should be restored. The country had 5,000 children in open-air nursery schools, but 174,000 between the ages of 2 and 4 were living in slum conditions. In these nursery schools rickets could be eliminated. The schools also eliminated grime, fear, and disease. Open-air nursery schools for 50,000 children would not cost more than £1,000,000, and would save other expenditure later on.

Replying to the debate Mr. RAMSBOTHAM asked for definite instances of education authorities which complained that schemes for new schools had been rejected. Considerable new building had taken place. Local authorities in Willesden, Birmingham, and elsewhere had used the services of experts from the National Institute of Industrial Psychology for testing children and giving vocational guidance. These methods probably were in their infancy, but it was worth while for local education authorities to look into the possibility of giving more scientific and efficacious vocational guidance than at present. Within the last month or two the Board had authorized two more nursery schools.

The motion for reduction of the Estimates was defeated, and the debate was adjourned, the Labour Opposition intimating that it might seek to discuss education again at some later date.

The Government's Milk Policy

Dr. WAITER ELLIOT, in committee of the whole House of Commons on May 31st, moved a resolution to authorize additional expenditure by any board administering a scheme under the Milk Marketing Act, and also to authorize payments for similar purposes out of moneys provided to the Government of Northern Ireland. The resolution also proposed to authorize the payment out of moneys provided by Parliament of sums not exceeding in the aggregate £750,000 to be applied by the Minister of Agriculture and Fisheries and the Secretary of State for Scotland, respectively, during a period of four consecutive years, with the object of securing, so far as practicable, that the milk supplied for human consumption in Great Britain was pure and free from the infection of any disease, and to provide for requiring boards administering milk marketing schemes to make payments after the end of that period to registered producers in respect of milk produced by them in such circumstances as might be prescribed by the Minister with that object. Money was also asked for contributing up to £1,000,000 in two years on a £ for £ basis towards the expenses incurred by Milk Marketing Boards in giving effect to approved arrangements for increasing the demand for milk, and to provide for regulating the manner in which milk is described for purposes of advertisement and sale.

Dr. Elliot said the annual value of the milk products with which the Ministry of Agriculture had to deal was £63,000,000. There were about 3,400,000 dairy cows in the country, and 320,000 persons engaged in the industry. Over 80 per cent. of the world's export of butter and over 50 per cent. of the world's export of cheese were sold in the United Kingdom. The Government sought a bigger consumption of milk, and, to secure that, a clean-up of the herds. Critics contended that it was a mistake to assist the manufacturing side of the industry, and that the money voted by Parliament should be devoted to increasing the consumption of liquid milk in schools. Some 10,000,000 gallons of milk a year were consumed in the schools by 1,000,000 children. That might perhaps be doubled in the first year, but milk used for manufacture in 1933 was estimated at 160,000,000 gallons. Even milk made into cheese on farms might amount to 45,000,000. Parliament must tackle this 200,000,000 gallons as well as the problem of greater consumption of liquid milk. It could not start a campaign for large consumption of milk except upon public confidence in the quality.

Eradication of Bovine Tuberculosis: Proposed Expenditure

This question had been exhaustively reviewed by the Committee of the Economic Advisory Council under the chairmanship of Sir F. G. Hopkins, whose report had been published.* Whatever might be the merits of pasteurization, a universal compulsory scheme was at present impracticable. The Hopkins Committee reported that the total eradication of bovine tuberculosis from all herds was the only complete solution of the problem of tuberculous milk. That solution could not be obtained for many years, and not without much expenditure, but the Government proposed to use £750,000 to make a start on this problem. It was impossible at present for the Milk Board to bear the cost of the scheme for establishing tubercle-free herds as well as the scheme for the Roll of Accredited Producers, which, following the recommendations of the Grigg report, was to be undertaken in England and Wales by the Milk Marketing Board without Government aid. To ensure continuity the Bill would enable Ministers to require the boards to continue this campaign. Boards would be required to submit, for the approval of the Government schemes for increasing the demand for milk, and a scheme would not be approved for grant on the £ for £ basis unless it contained provision for the supply of milk to schools at reduced rates. He had no need to argue the case for increasing the general consumption of milk. Even in winter this country had a 20 per cent. excess of milk over liquid requirements, and in summer the excess might rise to 40 per cent. Under the resolution before the House advances would be paid on milk sold under the marketing scheme for manufacture into cream, butter, cheese, milk powder, or condensed milk. He assumed that in the first year 160,000,000 to 180,000,000 gallons would qualify for advances under the resolution. The Government of Northern Ireland would shortly propose to carry through a similar series of reforms in some ways more drastic, grading the milk, cleaning up the herds, and providing a supply of milk to children in schools.

Mr. TOM WILLIAMS said the report of the Hopkins Committee indicted the dairy farmers, the large local authorities and all past Governments. It showed that 40 per cent. of the cows reacted to the tuberculin test, and that there was no sign of any diminution in the number. Of samples of milk taken in four large Scottish cities 10 per cent. were infected with tubercle bacilli. Of the local authority sample taken in England and Wales 7 per cent. were so infected. They could not hope to increase consumption of milk if they could guarantee a much purer supply. The Hopkins report showed that some county authorities were indifferent to securing a pure supply. Responsible people said between £30,000,000 and £50,000,000 would be required to clean up all the herds in the country. Dr. Elliot proposed to spend £170,000 yearly. What would he do with it? Would he provide Grade A (T.T.) milk, or provide a national veterinary inspectorate to inspect all the animals from time to time. There ought to be a national organized service of trained and qualified inspectors, and no county boundaries should

* See leading article, p. 1035.

interfere with their work. State funds should supply free milk to every elementary school child in the country. An investigation in Cardiff had shown that in a good middle-class house 3.8 pints of liquid milk were consumed per person weekly, in a good working-class area 1.87 pints, in a house under the new housing scheme 1.32 pints, and in a poor working-class house 1.1 pints. In the good working-class area 9 per cent. of the houses took no liquid milk; in the housing scheme houses 15 per cent., and in the poorer working-class houses 26 per cent. The sale of skimmed milk rose from 1.94 pints weekly per person in a good working-class house to 3.24 pints per person in a poor working-class house, though this last was not in a slum area. Moreover, the consumption of fresh liquid milk in a poor working-class house where there were children was only 1.1 pint per head, compared with 2.8 pints in a similar house without children. Of the children from houses which took no fresh liquid milk, only a few received milk at school. Low wages and unemployment had led to a decrease in milk consumption in certain areas. He need not quote from the British Medical Association's report on nutrition. Last year 900,000 children attending elementary schools in England and Wales received on an average one-third of a pint of milk per day, but paid 2s. a gallon for it, whereas the subsidized price at the factories was 5d. per gallon.

Mr. JAMES DE ROTHSCHILD said that medical opinion was not agreed on pasteurization, and that was one of the first things which should be examined during the campaign to increase the purity of milk. Pasteurization must never be regarded as a substitute for pure unprocessed milk, and the present conflict in medical opinion was worrying the milk-consuming public. Pasteurization allowed large distributors to foster low-grade production. The large distributors had followed this policy for years, and desired to continue it. Experiments to decide the relative values of raw and pasteurized milk could be conducted in schools over a long period. Such an experiment in the Llanarkshire schools had proved inconclusive. One on a large scale would give the public confidence when drinking milk. The campaign for purity could only succeed if the producers were rewarded with higher prices for better quality, but the distributors' margin for high quality milk could be drastically reduced because no processes were necessary. The present marketing scheme encouraged the production of low-grade milk. Mr. OSWALD LEWIS said it was undesirable to increase consumption of raw milk regardless of the possibility of spreading disease. At a later stage the Government would assure the House that it had in mind some definite qualifications with regard to the raw milk to be supplied in schools.

Immunization of Herds by Inoculation.

Sir FRANCIS ACLAND said he did not understand how bovine tuberculosis could be eradicated so long as the sale was permitted, as the Hopkins report proposed it should be, of milk uncertified—that was, of milk cleaner than it had to be now, but not derived from tubercle-free herds. He believed there was more chance of immunizing herds by inoculation than would appear from the Hopkins report. Research on immunization by inoculation should now be taken up with the greatest activity, and the supply of milk to schools should be delayed till they had a certainty of a tubercle-free supply. He backed the "children's minimum" policy, which asked for free provision of milk to all elementary school children, necessitous children under 5, and expectant and nursing mothers; but if they rushed into the proposal of distributing milk to schools some medical officer would say a child had acquired tuberculosis from milk, and that would be a fearful handicap. Many medical officers of health overdid their pursuit of pasteurization. Very little pasteurization was really fool-proof, and no one had laid down the exact conditions for it. Captain HENEGERS, as a Grade A producer, said that doctors had done much to kill production of clean milk in the United Kingdom, and, by crabbing the milk supply day in and day out, made it difficult for the Milk Marketing Board to raise the sales of liquid milk. Certified milk cost nearly 3d. a gallon extra to produce. The farmer must have a reward for producing cleaner milk. It would be a great thing to clear tuberculosis from this country, but the doctors had not given the milk producers a fair deal in representing the odds arising from tuberculosis. These were 2,200 to 1 in any year against any child getting tuberculosis

He supported the supply of fresh milk to children, citing experiments by Dr. Corry Mann at the Foundling Hospital as conclusive proof of the value of milk. He believed the Milk Marketing Board intended to extend the supply of cheap milk to factories, mines, and workshops. Admiral TAYLOR said the import of skimmed condensed milk should be prohibited. Although labelled "Unfit for babies," there was no guarantee that it would not be given them. What would Dr. Elliot do if factories in this country began to manufacture it?

The Medical View

Sir FRANCIS FREMANTLE said he spoke as a consultant medical officer of health, an active dairy farmer, and as president of the Central Council of Milk Recording Societies. As a medical officer of health he was always asked not to exaggerate, or perhaps not to emphasize, the danger of disease arising from milk. No one would wish to exaggerate the fears of the public, but agriculturists who tried to belittle the amount of disease did the worst disservice to the dairy industry. The People's League of Health had established a veterinary council and a medical science council, which established a combined commission to study the milk supply. They reported last year, and in April sent a deputation to the Minister of Health and to the Minister of Agriculture. Their careful conclusions were emphasized by the report of the Economic Committee of the Privy Council. They said that among the diseases conveyed from the cow to man were tuberculosis, undulant fever, and septic sore throat. The finding that at least 40 per cent. of the cows in this country were infected with tubercle had not been sufficiently met by those who talked for the dairy industry. That the nutritive value of milk was great the experiments of Dr. Mann with children in a Poor Law institution showed, but the nutritive value of milk must be considered in conjunction with its infectivity. It was absurd to say that the medical profession should not pay attention to the comparatively small proportion of tuberculous milk. It had to look at the sufferings of crippled children, to say nothing of the 2,000 deaths and 4,000 fresh cases every year. Pasteurization was perfectly simple, and did not destroy the nutritive qualities of the milk or its flavour. The difficulty of the machinery was solving itself, though on farms and out-of-the-way places there was danger in the use of this machinery. If milk was provided for schools it would be under the authority of the school medical officer or of the medical officer of health. They would consider the best way of protecting the milk given, and the greater number would say it was possible to pasteurize milk cheaply. In any case, the nutritive value of the milk would be to the advantage of the children, and these officers would desire to give to the children as large a supply as could be allotted. The short-term policy was the pasteurization or boiling of milk; the long-term policy the eradication of tubercle from the herds. The latter was most difficult, but could be done by a proper long-term policy, as set out in the reports he had mentioned. Greater support was needed for the veterinary profession in supervising cattle. The country required a system of tuberculin testing and of isolating tuberculous cattle from those which were not. The veterinary profession had not advanced with the times, and still suffered from want of proper training. The increase of educational facilities and the bringing up of a new generation of veterinary officers should receive consideration. They could not have proper veterinary inspection without adequate machinery of college and staff, and without bringing the best men into the profession. They must recognize the value of scientific work for prevention as well as disease in dairy cattle, and pay for the services of veterinary surgeons, who would do work on cattle such as medical officers of health had been organized for fifty years as a profession to do for human beings. Despite all difficulties, it would be an enormous gain if the proportion of food given to children every day in the form of milk could be increased, but there was danger in sudden change. In some homes the children might be deprived of other food because they were getting milk at school.

Mr. SKELTON, replying for the Government, said Sir Francis Acland need not fear there would be an inadequate supply of safe milk for the children of this country. There was a considerable and growing number of certified herds, and in London the great bulk of the milk, if not the whole, was

pasteurized. If the country could clean up the herds it would secure a degree of safety it could never attain by pasteurization, which had anxieties and dangers.

The House agreed with Dr. Elliot's resolution by 177 to 43. On June 1st the resolution was reported and the Milk Bill was brought in by Dr. Elliot. The Government proposed that the second reading debate should be on June 7th.

Lotteries Bill and Competitions in Aid of Hospitals

The House of Lords went into committee on the Betting and Lotteries Bill on May 30th, and continued discussion of that stage on May 31st. In Clause 24 (Restrictions on Certain Prize Competitions) Lord LUKE moved to insert a new subsection to ensure that a corporate body established before the passing of the Bill for a charitable purpose might conduct for any such purpose any competition in which success depended partly upon the exercise of skill, provided that the body had submitted to the chief officer of police in its area a copy of the rules and conditions of the competition, and an opinion of counsel that success in the competition depended to a substantial degree on the exercise of skill, and provided that the chief officer of police had not, within fourteen days of that submission, intimated his disagreement.

Lord Luke said his friends were anxious to preserve for hospitals this competition source of revenue, which seemed to be threatened by the clause. It was undesirable that voluntary workers, endeavouring to raise funds for a charity, should be open to prosecution and penalties when acting under the best legal advice, and that the charity for which they acted should lose thousands of pounds—spent in printing and advertising. The British Charities Association had run competitions for ten years. Last year it distributed £21,000 to hospitals, which brought its total distribution to 900 hospitals up to £250,000. The competitions had been part skill and part chance, and not one had been challenged in the courts. It was impossible to run a competition depending entirely on skill if prizes were to be distributed. Prize competitions for charity were popular and harmless, and charities could not afford at present to be deprived of this source of income. A hospital running a competition after this Bill passed, if unamended, would run the risk of an action to show whether the skill element was substantial. Lord LONDONBERRY, the Minister in charge of the Bill, said he could sympathize with Lord Luke's desire that the British Charities Association should be allowed to conduct competitions without danger of criminal proceedings, but the solution he proposed could not be entertained. Whether any competition was legal could be determined only by the courts. The legality would depend, to a certain extent, on the way the competition was conducted. Lord LUKE said he would leave the amendment and a consequential one over to the report stage.

Clause 24 was agreed to. The DUKE OF ATHOLL moved at the end to insert a new clause giving exemption for State and licensed lotteries. He said that recently he had allocated, from what had been described as a lottery, large sums of money to 118 hospitals and other institutions. All, including great London hospitals, had written grateful letters, and most expressed the hope that he would be able to inaugurate another scheme on similar lines for their benefit. He read a letter of thanks from the Treasurer's House of St. Thomas's Hospital. He saw no reason why lottery subscriptions should clash with voluntary subscriptions. His clause would enable the Government to authorize definite bodies such as hospitals to promote a lottery, or to appoint commissioners to carry out a lottery, or else authorize others to do it. The DUKE OF SUTCLIFF supported the amendment. The BISHOP OF WINCHESTER and Lord SOMERLEYTON opposed it. The Bishop said the majority of the hospitals were not asking for these lotteries. Lord Somerleyton said that voluntary hospitals in London were in a better position than for some time. Fewer had deficits.

Lord LONDONBERRY hoped the House would not accept the amendment. He was chairman of two hospitals in London, and opposed any organized system of lotteries for the purpose of supplementing hospital finance. If any system of lotteries were established the fountain of charity would dry up, as they heard it had in Ireland, where charitable contributions

formerly forthcoming were now non-existent. The Government agreed with the Royal Commission that large-scale lotteries, promoted by a statutory board for charitable objects or by individual charities under permits, were undesirable.

The House negatived the clause proposed by the Duke of Atholl, and completed the committee stage.

Experiments on Animals

Replying to Sir Robert Gower, on May 30th, Sir JOHN GUMMOUR stated that the number of instances during 1933 where inspectors witnessed the whole, or the initial procedure, of an experiment on a living animal was seventy. Twelve of these were under licence alone, three under Certificate B, and fifty-five under Certificate A. In addition, the inspectors in the course of their visits saw and examined many thousands of animals under experiment. The seventy experiments in question and the animals under experiment were seen in various registered places, a complete list of which would be given in the Annual Return. Information was not yet available as to how many experiments on animals were reported as performed during 1933.

Duty on Insulin Removed

On May 31st Sir Francis Fremantle, Dr. Howitt, and Captain Elliston, as a deputation from the Parliamentary Medical Committee, interviewed Mr. Neville Chamberlain about the removal of the duty on imported insulin. Mr. Chamberlain was accompanied by Mr. Geoffrey Shakespeare and Dr. Burgin. The deputation pointed out that the medical Members of Parliament were in a difficult position. Originally opposed to the tariff on insulin, they had gone into the matter thoroughly, and had finally agreed that the duty was necessary to enable British producers to compete with the Danes, who had buildings and equipment free and their product exempted from income tax. In Denmark raw pancreas and labour were both cheaper. Since the investigation no objection had been taken to the duty in the medical press, nor, so far as the deputation knew, from medical quarters. Nor was any objection on the score of prices taken by the Ministry of Health, the British Medical Association, or the medical profession generally. Under protection the price of British insulin had fallen. On the other hand, it was evident that the Danish producers were prepared to undersell the British manufacturers, however much these reduced the price, and would so secure the British market and the foreign trade which was now beginning. That involved a great danger of stopping research as well as production. The deputation, in fact, could see no reason for the change of Government policy. Mr. CHAMBERLAIN, in reply, showed that the imposition of the duty last February was not a Government decision, but the decision of the panel of experts that insulin was a fine chemical. He suggested that it was open for the British manufacturers to apply again to the Import Duties Advisory Board for any duty which was needed to protect their industry. He would not give any reason for the recent Government decision, except the general one that the cheaper insulin was, the better for the patients.

Debate in the Commons

On June 4th the House of Commons began consideration of the Finance Bill in Committee. Mr. H. WILLIAMS moved the deletion of Clause 5, which repealed the customs duty on insulin. He said that it was a little inappropriate, on the day that the announcement was made that Dr. Banting had been honoured, that the committee should be asked to pass a clause which would probably have the effect of handing over to a foreign monopoly the manufacture of insulin, which was discovered by this young and distinguished Canadian medical man. The increase in the duty on insulin from 10 to 33½ per cent. had not been followed by any rise in the price, and there was no evidence that any sufferer from diabetes in this country had been prejudiced. Dr. HOWITT said that to-day this country produced finer and purer insulin than any other country in the world. Our rivals were the Danes. People who said that insulin would become cheaper if the protection

was removed were wrong, for while the protection had existed insulin had steadily become cheaper and cheaper. Denmark was able to produce insulin more cheaply than we were, partly because of the subsidized nature of the manufacture, partly because of the ease with which the Danes could obtain the pancreas, and partly because of the cheapness of the pancreas. In the hospital with which he was connected only British insulin was used. That was not from patriotic reasons, but because the doctors said that it was the best. There was the danger that it might pay Denmark to sell her insulin here at a loss for a period if she could succeed in closing down our chemical works.

Mr. CHAMBERLAIN said that the imposition of the duty of 33½ per cent. on imported insulin under the Safeguarding of Industries Act was a kind of accident. Insulin was not picked out by the Government as being an article of such importance to the country in wartime that it must be safeguarded. The omission of insulin from the list of fine chemicals was challenged by the Association of British Chemical Manufacturers. The Board of Trade took up the challenge, and opposed the inclusion of insulin. The matter went before the tribunal, which decided that insulin must be included in the list. The purpose of the association was to establish the principle that certain biological products should be defined as fine chemicals; having established that principle by the decision of the tribunal it was not particularly interested in insulin. The clause in the Bill was not introduced because of any improper behaviour on the part of the chemical manufacturers in this country. It was very much to the credit of the British manufacturers that they had not only continually reduced the price of insulin, but had produced insulin of a quality which had established a special reputation here and abroad. Representations had been made to him to the effect that diabetics felt that the price of insulin was higher than it would have been but for this duty. There were a considerable number of people to whom insulin was a matter of life or death. If these people thought, even mistakenly, that they had to pay more for it than was necessary by reason of the duty they would have a just cause of complaint. Since the announcement that the duty was to be repealed there had been a further reduction in price. The repeal of the duty left the British manufacturer free to make application to the Import Duties Advisory Committee for a duty on imported insulin. There would be an inquiry into the facts of the case, and if the committee came to the conclusion that diabetics would suffer they would, he imagined, make a recommendation accordingly.

The clause was ordered to stand part of the Bill.

Water in Swimming Baths.—Mr. SHAKESPEARE told Mr. D. G. Somerville, on May 31st, that a report on the purification of water in swimming baths was prepared by the Ministry of Health in 1929. This report emphasized the importance of clean water in public baths, and explained the best method of purification. Local authorities were aware of the recommendations in the report, to which attention would again be called in the forthcoming annual report of the Ministry. In the case of swimming pools not belonging to local authorities, the water, if impure, would constitute a nuisance under the Public Health Act, and local authorities would have power to deal with it.

Specialists on Royal Commissions.—In reply to Mr. Chorlton, on May 31st, Mr. BALDWIN said he had noted the views expressed by the Parliamentary Science Committee in a letter dated May 8th, which urged the inclusion of scientists and technicians in the personnel of all Royal Commissions, Departmental Committees, and other committees dealing with scientific and technical matters. He said it would be inadvisable to lay down a general rule. The importance of including scientists and technicians in appropriate cases was, and would be, borne in mind.

Vaccination in the Navy.—On June 4th Sir B. EYRES-MOSSELL informed Mr. Groves that it was not the practice to allow persons to enter the Navy who were conscientious objectors to vaccination. All candidates on entry were required to declare their willingness to be vaccinated, or revaccinated and inoculated if necessary. Otherwise they were not accepted for entry.

Medical News

The Queen has consented to open the new Students' Hostel at the London Hospital Medical College on Tuesday, July 3rd, at 3.30 p.m.

The Earl of Derby will distribute the prizes at St. Thomas's Hospital Medical School in the Governors' Hall, on Tuesday, June 26th, at 3 p.m. There will be tea and music on the terrace.

The annual general meeting of the British Science Guild will be held on Tuesday, June 12th, at 4 p.m., at the Royal Society of Arts, John Street, Adelphi, with the president, Lord Melchett, in the chair. The meeting will be followed by a popular lecture (illustrated by lantern slides and experiments) on "Friction," by Professor E. N. da C. Andrade, D.Sc. Tickets for the meeting and lecture may be obtained, free of charge, from the secretary of the guild; 6, John Street, Adelphi, W.C.2.

An exhibition, organized by the Rubber Growers' Association, will be held at the Hotel Metropole, Northumberland Avenue, W.C., on June 13th, 14th, 15th, and 16th, from noon to 8 p.m. Admission free.

The Fellowship of Medicine (1, Wimpole Street, W.) announces a lecture-demonstration on "Oedema and Diuretics" at 11, Chandos Street, W., on June 12th, and another, on "Renal Insufficiency," for June 19th. There will be a course in proctology at St. Mark's Hospital from June 11th to 16th, and a course in medicine, surgery, and the specialties at the Prince of Wales's Hospital from June 11th to 23rd; the latter will be repeated from June 25th to July 7th. Forthcoming courses include cardiology at the National Heart Hospital, June 25th to July 7th; diseases of children at the Children's Clinic, June 25th to July 7th; ophthalmology at the Central London Ophthalmic Hospital, July 2nd to 7th; and a week-end course in medicine and surgery at the Metropolitan Hospital, June 30th and July 1st.

The Faculty of Medicine of the University of Paris has arranged a post-graduate course in cancer for the month June 11th to July 12th. In addition to formal lectures, discussions, and clinics in the mornings, there will be demonstrations of surgical, x-ray, and radium treatment. The fee is 300 francs, and a certificate will be awarded at the end of the course. Inquiries should be directed to the Faculty of Medicine, Salle Bédard, Paris.

The next conference of the British Health Resorts Association will be held at Cromer, at the invitation of the urban district council, supported by the local medical practitioners and the Norfolk Branch of the British Medical Association, from Friday, June 29th, to Sunday, July 1st. There will be discussions on "The Seaside Resort in the Treatment of Respiratory Diseases," to be opened by Dr. R. A. Young, followed by Dr. L. S. T. Burrell, and "Climatic and Allied Factors in the Incidence of Disease and its Treatment on the East Anglian Coast," to be opened by Dr. R. Fortescue Fox.

A congress on *B. coli* infections and intestinal intoxications will be held at Châtel-Guyon on September 23rd and 24th, and will comprise medical, surgical, therapeutic, and hydrological sections. Among the topics to be considered are septicæmia of *B. coli* aetiology, also the diseases of children caused by this organism, and its localization in the genital organs. Other subjects for discussion include hydromineral therapy in intestinal infections and intoxications, nervous complications in these conditions, and the gynaecological aspects of *B. coli* infection. The fee for membership of the congress is 50 francs. Specially reduced railway fares and hotel charges are available for those who attend. Further information is obtainable from the administrative secretary of the congress, M. Juin, or Dr. P. Balme, Les Grandes Thermes, Châtel-Guyon.

The third French Congress of Gynaecology will be held in Paris from July 7th to 10th, with Professor Koenig of Geneva as president of honour, and Dr. André Binet of Nancy as president.

The King has approved the grant of the Polar Medal in bronze, with clasp inscribed "Antarctic 1929-31," to Dr. William W. Ingram, M.C., who was a member of the British, Australian, and New Zealand Antarctic Research Expedition, 1929-31.

Owing to the present financial crisis the Austrian Minister of Education has decided to reduce the number of university institutes. One of the two oto-rhino-laryngological clinics has already been closed, as well as one of the three gynaecological clinics.

A lecture on the theory and practice of contraception will be given to medical students and practitioners by Dr. Gladys Cox on Tuesday, June 12th, at 6 p.m., at the Walworth Women's Welfare Centre, 153A, East Street, S.E.17. Tickets must be applied for in advance.

The second centenary of the birth of the Spanish surgeon Antonio de Gimbernat is being celebrated this month by the Surgical Society of Catalonia, when a prize of 1,500 pesetas will be awarded for the best biography of Gimbernat.

The summary of deaths among medical practitioners during 1933, published in the *Journal of the American Medical Association*, shows that the four commonest causes of death were heart disease (1,131), cerebral haemorrhage (360), pneumonia (313), and cancer (286).

The prize of 5,000 Belgian francs offered by *Bruxelles-Médical* for the best work published in its columns during 1933 has been divided between Professor Bessemans, rector of Ghent University, and Dr. Dumont, a colonial medical officer.

Dr. Jean Charcot, the well-known explorer and member of the Académie de Médecine, has been nominated Grand Officer of the Legion of Honour.

Professor W. His has been awarded the Goethe Medal and nominated honorary doctor of philosophy in the University of Berlin.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, Antology Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westcent, London.

MEDICAL SECRETARY, Mediscera Westcent, London.

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: Bacillus, Dublin; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumshugg Gardens, Edinburgh (telegrams: Associate, Edinburgh; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

Orchitis After Prostatectomy

"X. Y. Z." writes: A man aged 72 had a suprapubic prostatectomy done a year ago for hypertrophy. Prior to his operation he had frequent acute attacks of epididymo-orchitis. These attacks still persist. Can any reader suggest what form of treatment one might adopt? The patient is strong and active; no history of gonorrhoea, or anything to suggest malignancy.

Worms in White Fish

"RURAL G.P." writes from Ireland: I have on several occasions found small "wire-worms" in the flesh of white fish such as codling. Are such worms found in all fish or in some only; are they completely killed by ordinary cooking; and, if swallowed alive, would they become parasitical in man?

Movement of Needles in the Tissues

Dr. C. BELCHER (Birmingham) writes in reply to "Sceptic" (May 12th, p. 880), who asks whether foreign bodies move in the tissues: The following cases will prove that such is a fact. Foreign bodies do travel from the original entry. A youth consulted me for a pain in his right side, not severe, but worse at one time than another. On his first visit I found little to account for his trouble. On his second visit I went over him more carefully, and passing my hand over his side felt a prick. I examined the part again, and still experienced the sharp prick like that of a pin; and, looking at the spot; which was in the posterior axillary line at a level with the first lumbar vertebra, I saw a small discoloured spot, the point of a pin or needle; but he could give me no information as to how it got there. The following evening he returned, with his mother. I explained to her what I had discovered and asked permission to remove it, which I did; it was a darning needle about two inches long, blackened, but quite serviceable. Immediately the woman saw it she recognized it, and exclaimed "I remember it very well; when he was a baby, not having a safety-pin handy, I fastened his shawl in front with the needle, put him in the cradle in a hurry as I was called away, and forgot it until I came to undress him and then thought about the needle. Look as I would I could not find it." The other case was a man with a small beer-shop, who came to me complaining of numbness and tingling of the fingers of his left hand. I could see nothing in the hand to account for it, and so examined his arm and upper arm; when I put my hand in his left axilla I felt a slight ridge, and when I pressed upon it he said that this started the tingling in his fingers. I recognized that whatever it was this was the cause of his trouble, and intimated that he had got some substance into his axilla and asked him how it had got there. He refused to admit anything being there; never, to his knowledge, had he had anything go into his side. I suggested he might let me put a needle under the skin (as the foreign body was only skin deep), which he did, and I distinctly felt a hard substance beneath. Without any anaesthetic, local or otherwise, I made a small incision, and with the forceps withdrew a triangular splinter of glass one and a half inches long. I showed it to him, and he was dumbfounded. On coming back to have it dressed he told me he had talked it over with his wife, when she remembered that on a windy day the previous summer the glass door leading to the shop had blown to and he had put his shoulder to it to prevent slamming, but he had smashed the glass pane. He felt nothing, but she noticed a spot of blood on the top of the shoulder of his white shirt afterwards, and mentioned it to him, but they could see no wound.

Income Tax

Review of Past Years

"JUNIOR" asks how many years is the inspector authorized to go back for investigation of accounts.

* * The Income Tax Acts do not give the inspector much authority in the matter, but they give the Commissioners the right of making assessments for the six previous years. In certain circumstances those assessments may be confirmed wholly or partially in treble duty. Consequently it is advisable to meet any reasonable requests by the inspector as there is in the background the possibility that refusal may lead to action by the Commissioners, which may in effect enforce production of the evidence requested by the inspector.

Motor Car Transactions

"W. A." bought a car in 1927 for £685 and sold it in May, 1933, for £35, the reduced value then being £231. He bought a new car for £405 in replacement, but sold it in October for £295, and may not buy another. He has been allowed depreciation at 15 per cent. per annum.

* * He is entitled to obsolescence allowance in respect of the replacement in May, 1933, the amount being £231 - £35 = £196. That sum can be treated as a professional expense of the year 1933. No obsolescence allowance is due in respect of the subsequent transaction unless and until another car is purchased in replacement of the one sold in October, 1933.

Purchase of Drugs

"F. L." purchased a share in a practice in October, 1932, and paid £52 to his predecessor for a share in the drugs. Can he claim that that payment is an allowable expense.

** "F. L.'s" liability is determined by his share of the profits of the practice, and, presumably, the cost of the drugs used is charged in arriving at the amount of the firm's profits, and his special payment cannot be deducted again. In effect it is a capital payment so far as "F. L." is concerned, and is part of the cost to him of acquiring his share in the practice.

LETTERS, NOTES, ETC.

Local Anaesthetic for Myringotomy

Dr. ARTHUR MURPHY (Brisbane) writes: In the *Journal of February 10th* (p. 262), Dr. John M. Dewar of Edinburgh asks in a letter for the means of incising the membrum tympani under local anaesthesia. May I assure him that the following local anaesthetic will secure the painlessness of the proceeding within ten minutes, often less. The criterion is that the inflamed membrane goes white in colour, which in my experience it always does.

Tutocaine, menthol, acid carbolic. crystals, aa grains 15.
Alcohol 42 per cent., aq. dest., aa m8.

Powder the menthol and mix the tutocaine with it in a mortar. Then, in a glass, add first the carbolic acid, then the spirit, and then the water. In chemically pure glass bottles it keeps indefinitely. Apply on an applicator directly to the ear drum over the area to be incised.

** Care should be taken that this preparation is not applied to the skin of the auditory meatus.

Cost of Hypodermic Needles

Dr. T. D. ROSS (Cathcart, Glasgow) writes: A patient of mine who uses insulin daily has been complaining about the high cost of hypodermic needles. He has made inquiries and finds that the wholesale prices charged to chemists for these are: *British make* (stainless steel) 17s. 6d. per gross, or about 1½d. each; *German make* (nickel plated) 10s. to 12s. per gross, or ¾d. to 1d. each. The prices being charged by chemists are 6d. for one only or 5d. each if purchasing half a dozen lots or more of British needles, and 3½d. each for German needles. My patient much prefers the British article. If the above wholesale prices are correct it would appear that the retailer is making an exorbitant profit.

Pernicious Anaemia in the Asiatic

"M.D. (Madras)" writes: The naïve assertion by Dr. Eric C. Spaar of Colombo, in your issue of March 31st (p. 578), about the non-occurrence of pernicious anaemia in the Asiatic reminds one of the recent controversy in the correspondence columns of the *Journal* on the incidence of rheumatic infection in the Tropics. I believe that Davidson, in his valuable monograph on pernicious anaemia, does mention the rarity of the disease in India. Most practitioners of standing in India should be able to testify to the contrary. I have myself, in my limited hospital work, come across at least half a dozen cases that will satisfy the most exacting of modern criteria in diagnosis of pernicious anaemia, and have seen undoubted cases of subacute combined degeneration. I deplore the lack of case reports with full details of investigation. I hope that the growing tendency of expression in India will dispel in time many ill-founded textbook notions on diseases in this country.

Martyrdom-by-Sandwiches

Dr. DOUGLAS ANDERSON, a member of the New South Wales Branch of the Association, now in England, writes. In order to protest against what they interpret as the contention of the B.M.A. that a working man can live on 5s. 10½d. a week, and on the other hand the extravagant living at the University, five Oxford undergraduates have formed the Martyrs' Memorial Dining Club. The five members have met nightly to consume ten penn'orth of sandwiches and coffee served from a coffee stall, and they have an anthem designed to be chanted as they assemble, running:

Here where the Martyrs resolute and godly
Escaped through flame to Pit that flames for all,
We pale and studious denizens of Bodley
Receive our sustenance from yonder stall.

Now, however, at the end of term, it is reported that the Martyrs, despite their privations, are looking remarkably fit and well. Might we not add another verse to their anthem?

After a week of martyrdom-by-sandwiches

The five have not appeared to waste away;

Indeed they've thriven as they had not planned, which is

A sign one shouldn't doubt the B.M.A.

The Word "Clinic"

Dr. W. W. SHRUBSHALL, D.P.H. (Burgess Hill, Sussex), writes: In your issue of May 19th I notice with satisfaction the protest against the misuse of the word "clinic," suitably expressed by Dr. L. Firman-Edwards. I well remember when the importation of this word with its modern meaning, probably from America, was first noticeable, and the derision in which it was then held by some of my confreres. The scorn for it in its modern misuse was, unfortunately, not sufficient to inhibit its growth. Your correspondent's suggested use of the word "centre" in place of "clinic" in this connexion appears to be quite appropriate.

Anglo-American Continental Medical Society

Dr. TOM A. WILLIAMS informs us that the officers of the Anglo-American Continental Medical Society commissioned him to arrange a gathering of the society and its friends in the British Medical Association during the Bournemouth meeting. In consultation with those responsible for organizing the meeting, Friday, July 27th, at 12.30 p.m. for luncheon in the Pavilion, has been selected. The society feels that all its members who are eligible should belong to the B.M.A., in order to keep in touch with the profession at home and in their turn to keep it acquainted with the fact that there are still on the Riviera, and throughout Europe and the contiguous countries, practitioners competent to deal with English-speaking people who have the misfortune to be ill while abroad. To that end it wishes not only to get into touch with former friends, but to form new connexions in England by means of this gathering at Bournemouth. Those wishing to attend should communicate with Dr. Tom Williams, before July 23rd, at the Royal Societies Club, St. James's Street, S.W.1.

Abstracts for Filing

The *Archivos Latino Americanos de Cardiología y Hematología*, a bi-monthly periodical published in Mexico, adopts an excellent practice in the publication of its epitome of current medical literature. Abstracts from foreign journals are printed on specially stiffened coloured paper which, readily detachable, and bearing a reference number at the top right-hand corner, can be placed straight into a card-index filing cabinet. Use of the reverse side of each sheet allows for an overflow of subject-matter in the case of a long abstract, and enables three abstracts to be printed on a uniform amount of space on each page.

London for the Visitor

London is expected by travel authorities to attract greater numbers of visitors this summer than ever before, from the rest of Britain and from over-seas. In readiness for their arrival the Automobile Association has produced for the first time an *A.A. London Guide*. This booklet is built round a general descriptive article suggesting convenient excursions, chiefly afoot, and street maps of the City and West End are supplemented with a cross-referenced list of principal streets. It may be obtained free by members of the A.A. on application to Fanum House, New Coventry Street, W.1.

Toxins and Emulsions: Correction

We regret that line 11 of the third paragraph in Dr. V. G. Walsh and Dr. A. C. Frazer's letter (June 2nd, p. 1004) was printed incorrectly by the accidental substitution of line 14 of the same paragraph. The two sentences involved in the error should have read: "Thus we can safely eliminate the solubility idea once and for all. Adsorption is the only phenomenon necessary to explain these results."

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 64, 65, 66, 67, 68, 69, 72, and 73 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 70 and 71.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 292.

BRITISH MEDICAL JOURNAL

LONDON: SATURDAY, JUNE 16th, 1934

PREGNANCY DIAGNOSIS IN THEORY AND PRACTICE*

BY

J. M. ROBSON, M.D., M.Sc.

BEIT MEMORIAL RESEARCH FELLOW

Recent work in sex physiology has shown that two types of hormones are excreted in the urine of the female subject at various stages of the life cycle. They are: (1) hormones produced by the ovaries (and during pregnancy probably by the placenta), exerting their effect upon the secondary sex organs and having no direct action on the gonads themselves; and (2) hormones capable of influencing the morphological and secretory activity of the gonads, and produced by the anterior lobe of the pituitary (and possibly by the placenta during pregnancy). The former group includes a number of substances to which the name of oestrin has been given, while the term "gonadotropic hormones" describes those substances which are not produced in the gonads themselves, but activate these organs. Oestrin is found in the urine for some days after birth, during the whole of the period of sexual activity, and for at least some years following the menopause. The gonadotropic hormones are excreted in the urine for some days after birth, and during the whole life cycle after the onset of puberty.

The excretion of both these types of hormones is very markedly increased during pregnancy, the amounts found in the urine being largely in excess of those present under any other physiological conditions, and the diagnosis of gestation is essentially dependent upon this fact. But whereas conception is almost immediately succeeded by a tremendous increase in the gonadotropic hormone excretion, which reaches its maximum in the early stages of pregnancy, the increase in the elimination of oestrin occurs more slowly, and is gradual and progressive throughout gestation, reaching a maximum at parturition. The gonadotropic hormone content of the urine, rather than its oestrin content, has therefore largely been employed for diagnostic purposes, as it is more especially in the early stages of gestation that such a test is of greatest value to the clinician. In the mare, however, oestrin is the chief hormone excreted in the urine during pregnancy, and the diagnosis depends upon the recognition of certain quantities of the oestrous hormone (Crew, Miller, and Anderson, 1931).

Tests for Gonadotropic Hormones

Now a number of methods have been elaborated for the determination of the gonadotropic hormone content of fluids and tissues. These tests are dependent upon morphological or secretory changes induced in the organs of injected animals by the material that is being tested. The alterations that may be observed in the gonads of experimental animals subject to the action of gonadotropic hormones are numerous, and may be classified as follows.

	Female	Male
Morphological	1. Follicular maturation 2. Ovulation 3. Formation of corpora lutea (a) True corpora lutea (b) Atretic corpora lutea (c) Corpora haemorrhagica 4. Formation of blood spots	Increase in size affecting apparently chiefly the interstitial tissue
	1. Secretion of oestrin 2. Secretion of corpus luteum hormones	Secretion of male hormone

There has been much controversy as to whether all these effects are due to a single gonadotropic hormone acting in different concentrations and under different conditions, or whether two or more gonadotropic hormones are responsible for the various effects observed. A careful analysis of the results obtained by a number of investigators (Aschheim, 1933; Evans, 1933; Hisaw *et al.*, 1933; Coester, 1932; etc.) strongly suggests that more than one substance is concerned in the control of the various changes produced in the gonads. Moreover, it can also be asserted that extracts containing gonadotropic hormones and obtained from different sources do not all produce the same set of reactions in the gonads. For example, recent work is showing that extracts made from the pituitary gland possess properties which are not shared by those made from pregnancy urine.

Action of Hormones in Urine

But we are more particularly concerned with extracts from urine excreted under different physiological and pathological conditions, and it appears, on the whole, probable that two types of extracts can be obtained—namely: (1) extracts which produce chiefly follicular maturation and oestrin secretion; and (2) extracts which lead to the formation of ovarian haemorrhages and to the production of luteal tissue and of ovulation.

Now the substances obtained from the urine of female subjects apart from pregnancy conform, on the whole, to Type 1, while the gonadotropic hormones produced during gestation are, as a rule, capable of bringing about the effects described under Type 2. In practice, in the estimation of gonadotropic hormone content of urine, which constitutes pregnancy diagnosis, certain reactions induced in the gonads of the injected animals have been arbitrarily chosen as end-points. And although some observers have attributed most of these reactions to a definite gonadotropic hormone (the luteinizing hormone, prolactin B) it must be emphasized that such an assumption, in so far as it relates to pregnancy diagnosis, is at present chiefly

* A British Medical Association Lecture delivered to the City of Aberdeen Division on April 12th, 1934.

of theoretical interest. Of practical importance is the elaboration of a method which will give a positive result with the amount of gonadotropic hormones present in a definite quantity of urine obtained from a pregnant subject, and a negative result when a similar amount of urine from a non-pregnant subject is employed. Such an end has been attained by a variety of techniques, among which the most important are: (1) the Aschheim-Zondek test, (2) the Friedman test, and (3) the Brouha test. This last relies upon the action of the gonadotropic hormones in stimulating (in male animals) the production by the testes of the male hormone which causes growth of the vesiculæ seminales; the test, which is performed on male mice, does not give as reliable results as the other methods. Lately Bellerby (1934) has described a simple test which depends on the induction of ovulation by the injection of gonadotropic substances in *Xenopus*, kept under standard conditions. Results are obtained within nine hours—a much shorter interval than that required for the other tests. Further data are necessary before the value of this method can be assessed.

The Aschheim-Zondek Test

The Aschheim-Zondek test is performed on immature female mice about three weeks old, and depends on the production in the ovaries of certain definite changes. As the urine to be examined may be toxic to the mice, which may interfere with the test, it has to undergo some treatment previous to its injection. Zondek has suggested extracting the toxic substances by shaking the urine with ether, the ethereal fraction then being discarded; and this method has proved very successful. The method employed by the Edinburgh Pregnancy Diagnosis Station has also given very satisfactory results, and is performed as follows:

To each 25 c.cm. of urine one gram of sulphosalicylic acid is added. The urine is allowed to stand for thirty minutes, with occasional shaking. It is then passed through a filter paper, and the filtrate is neutralized with sodium bicarbonate and kept for injection.

Five mice are used for the test, and each animal receives six injections of 0.4 c.cm. of treated urine: the injections are spread over three days—that is, two injections per day, morning and evening. On the morning of the fifth day after the first injection (satisfactory results can also be obtained 100 hours after the first injection) the animals are killed and the ovaries examined macroscopically, and, if necessary, under the binocular microscope. The following changes may be observed in the ovaries: (1) *corpora lutea*—these are usually easily recognizable; (2) *blood spots*—these may be large and easily seen, but on the other hand they may be minute and may have to be carefully looked for (steeping the ovaries in glycerin for a few minutes renders evident any small blood spots which may otherwise not easily be detected); (3) *enlarged follicles*—constituting the so-called "white spots." The presence in one or more ovaries in the five animals of a corpus luteum or blood spot (or both) constitutes a positive diagnosis. The presence of enlarged follicles is, according to the arbitrary standards, a negative finding, but it has, nevertheless, been found advisable to repeat the test in such cases, as occasionally it does represent a positive diagnosis.

The period of time (four to five days) necessary for the diagnosis does not, in the majority of cases, present any drawback, but it is sometimes desirable to secure a result more rapidly. A number of observers have attempted to develop a rapid test by modifying the Aschheim-Zondek technique (Zondek, 1931; Aberson, 1931; Lassen, 1932), but there is at present no really satisfactory evidence that any of these modifications possess a sufficiently high degree of reliability. On the other hand, the use of the rabbit as a test animal has led to a technique which gives reliable results within much shorter intervals.

The Friedman Test

Friedman (1929) found that the intravenous injection of urine from a pregnant subject into rabbits was followed by ovulation in the ovary in a period of twenty-four hours or less, and immediately realized the importance of this finding in relation to pregnancy diagnosis. The rabbit never (or very rarely) ovulates spontaneously, and hence, if mature animals are segregated, they are suitable for the test. Provided that they are more than 3 months old ovulation can also be induced in immature animals, which are so suitable in many ways for the test that they have been very generally employed.

Three types of technique have been used—namely, (1) a single injection of urine, (2) multiple injections of urine, and (3) the injection of a concentrated preparation of the active gonadotropic substances made from the urine to be tested.

The first two of these methods have apparently yielded very good results in the hands of several observers, although it is to be noted that in many cases accurate results cannot be secured in less than forty-eight hours (for example, Ehrhardt, 1932). These methods were, at first tried at the station in Edinburgh, but were not found sufficiently satisfactory. This may be due to the interval elapsing between the collection of the urine and its receipt for examination being longer than has been the case with other investigators. We therefore decided to elaborate a method which would give results possessing a high degree of reliability within twenty-four hours, if possible. And the method I am now using as a routine in Edinburgh is actually capable of doing so.

The active gonadotropic hormones are obtained from the urine in the following manner.

To 50 c.cm. of the urine is added 50 c.cm. of rectified spirit, and the mixture is allowed to stand for some minutes. The precipitate, which consists of inactive material, is centrifuged off and discarded; 150 c.cm. of rectified spirit is then added to the supernatant fluid. This brings down the active factors; the precipitate is again centrifuged off, and the supernatant fluid is now discarded. The precipitate is extracted with ether to remove any remaining toxic substances, and the fraction not removed by the ether is dissolved in 5 c.cm. of saline and neutralized; 3 c.cm. of this solution is injected intravenously, and the animal is operated on twenty-four hours later. If for any reason the reaction is doubtful (in about 10 to 20 per cent. of cases), then the remaining 2 c.cm. is injected, and the animal is again operated on after a further interval of twenty-four hours.

Unless a definite positive test is given by one ovary both ovaries are always inspected. A positive diagnosis is returned if (1) one or more ovulated follicles, or (2) one or more haemorrhagic follicles, are observed.

Both ovulated and haemorrhagic follicles may, of course, be present in the same animal. In the great majority of cases (about 80 to 90 per cent.) the result is definite within twenty-four hours. Uncertainty at this stage may arise for these reasons: sometimes the ovaries of normal rabbits contain small blood spots; occasionally, too, after the injection of gonadotropic hormone, the only effect after twenty-four hours is the production of a blood spot. Hence if such a condition is found in the ovary on inspection it may be difficult to decide whether the blood spot has arisen as a result of the injection or independently of it. Twenty-four hours later, however, the question can be decided, as, with the method employed, a more marked effect is seen in the ovary if the test is positive. Rarely, too, follicular maturation only is seen twenty-four hours after the injection, and in such cases a further examination at forty-eight hours is undertaken.

Fortunately the above difficulties do not often arise, and it is only in some 10 to 20 per cent. of the cases that it is not possible to give a diagnosis within twenty-four hours.

Reliability of Tests

It is important to determine what degree of reliability can be achieved with the Friedman test, and how this compares with the Aschheim-Zondek test. Mack and Agnew (1934) have recently reviewed the literature on the subject and classified the results in several thousands of cases, including a large number of their own. The Aschheim-Zondek test gave a mean accuracy of 96.6 per cent. in 8,685 cases described by various investigators, while an accuracy of 98.5 per cent. was obtained by means of the Friedman test in 1,899 cases. In their own cases they were able to get slightly better results with the Friedman than with the Aschheim-Zondek test. At the Edinburgh station 3,151 A.Z. tests, controlled by clinical findings, were performed during the period 1930 to 1933, and the actual error was 1.75 per cent.—an accuracy of 98.25 per cent.

Table Showing the Results Obtained with the Aschheim-Zondek and Friedman Tests on a number of Cases Tested in Edinburgh

Cases	Aschheim-Zondek Test		Friedman Test	
	Positive	Negative	Positive	Negative
Definitely pregnant ...	74	2	75	1
Definitely non-pregnant ...	1	66	1	65
Abortion ...	1	5	5	1
"Delayed menstruation" ...	0	2	2	0

We have also examined 151 cases with both the rabbit and the mouse test; the data are shown in the table. In 138 cases (seventy-three pregnant and sixty-five non-pregnant) the results of both tests were in agreement. Six cases of early abortion urine were also examined, and in five of these the Friedman method gave a positive result while the Aschheim-Zondek was negative. In one case the Friedman test was negative and the Aschheim-Zondek positive. In two cases in which menstruation was delayed for some time the Aschheim-Zondek test was negative while the Friedman yielded a positive result. The possibility that these apparently false positives were due to undetected early abortions cannot be excluded. Lastly, there were two cases in which the Friedman test was definitely wrong (one false positive and one false negative), and three cases in which the Aschheim-Zondek test was definitely wrong (two false negatives and one false positive). These results are substantially similar to those previously reported by a number of observers, and agree in showing that there is little difference between the reliability of the Aschheim-Zondek and the Friedman tests.

Validity of the Tests

The various diagnoses described represent tests, not for pregnancy, but for the presence in the fluid examined of gonadotropic hormones capable, in the definite amounts injected, of causing certain alterations. A positive result, therefore, means no more than that those amounts of hormone are present in the quantities of fluid examined, and it is then necessary to make a differential diagnosis between the various conditions in which these hormones may be excreted. It must be emphasized, however, that in the great majority of cases a positive test does actually indicate gestation.

The increased excretion of gonadotropic hormones occurs not only during a normal pregnancy but also during ectopic gestations. It commences very shortly after the embedding of the fertilized ovum, and continues as long as the living products of conception or chorionic elements are in biological contact with the maternal tissues. Positive effects have been obtained with urine collected

even before the missed menstruation. If pregnancy is interrupted the excretion of gonadotropic hormones rapidly falls, and the test becomes negative within a few days.

The pregnancy test is also positive in cases of hydatidiform mole and chorion epithelioma: indeed, in these cases the excretion of gonadotropic hormones is usually at a much higher level than during pregnancy, the amount excreted attaining, in some instances, several 100,000 units per day (Ehrhardt, 1930). When either of these conditions is suspected a quantitative estimation of the gonadotropic content of the urine may be carried out, and a finding of 100,000 or more units per litre strongly suggests that a normal gestation is not present. A few cases of malignant disease have also been recorded in which the urine gave a positive pregnancy diagnosis test.

After the menopause the excretion of gonadotropic hormones is markedly increased, but extracts usually only cause follicular maturation effects. At times such urines give positive Aschheim-Zondek reactions, and this also applies to the urine excreted by patients after operative or radiological castration (Brandstrup and Lassen, 1933).

Finally, it is of interest to note that in normal pregnancy the excretion of gonadotropic hormones may occasionally fall to such a low level that the pregnancy test becomes negative (Runge, Hartman, and Sievers, 1932). A negative test in the presence of decidual tissue may also be observed in rare cases in which the tissue between the embryonic and maternal circulation is fibrosed (Kleine, 1933). A similar fibrosis has been described by Phillip (1931) in two cases of hydatidiform mole in which the Aschheim-Zondek test was negative.

The second (1934) edition of the *List of International Fellowships for Research*, issued by the International Federation of University Women (Crosby Hall, Cheyne Walk, S.W.3; price 2s.), contains a useful index which enables quick reference to be made to those which relate to specific subjects. The list is classified under three headings: fellowships open to graduates of all countries irrespective of nationality; those for study abroad which are restricted to students from two or more specified countries; and those which are limited to students of one specified country. Most of the fellowships are without sex discrimination, but the exceptions to this rule are duly specified. No attempt has been made to give an exhaustive description of the exchanges which can be arranged for students and members of faculties of the European universities, since this has been already made available with much additional information in the hand book published by the League of Nations Institute of Intellectual Co-operation. The sole intention of the present list is to place at the disposal of students in a readily accessible form such knowledge as will enable them to pursue post-graduate work in foreign countries. Most of the fellowships and scholarships are intended to advanced post-graduate or research work, and scholarship for undergraduate study are not included, except where the opportunities offered are equally available for both graduates and undergraduates.

ANEURYSM OF THE INNOMINATE ARTERY TREATED BY PROXIMAL LIGATURE

BY

H. S. SOUTTAR, C.B.E., D.M., M.Ch., F.R.C.S.

The surgical treatment of an innominate aneurysm is a sufficiently unusual event to be worthy of record, and the case to be described presented several features of interest.

History of Case

The patient, a Frenchwoman aged 62, was sent to me by Dr. Melsome of Bath, whom she had consulted only seven months before for a pulsating swelling in the right side of the neck just above the clavicle. She was a finely built woman of exceptional muscular development and unusual energy, for which she found an ample outlet in her profession as a masseuse. Apart from the swelling in the neck, she was in excellent health, and of unusual vigour for her age. The pulse was equal on the two sides, regular, and of good volume. Her blood vessels were somewhat thickened and tortuous, and her blood pressure was 160/100, although she had been for some weeks at absolute rest. The Wassermann reaction was negative.

On examination a pulsating swelling could be seen extending about an inch above the right clavicle. The swelling was visible even when she lay at rest in bed, but it became much more prominent on slight exertion, when the expansile character of the pulsation became very obvious. X-ray examination showed slight enlargement of the ascending aorta, with increased prominence of the aortic knuckle and a loss of translucency at the right apex of the lung; it was thought that this might be due to an aneurysm, although no definite outline could be seen. She was kept under observation, at absolute rest, for a fortnight, but as no diminution of the swelling occurred it was decided to operate.

The Operation

On May 24th, 1933, the operation was undertaken under local anaesthesia. After wide infiltration with novocain 1/2 per cent. and adrenaline, an incision four inches in length was made just above the right clavicle, dividing the platysma and the clavicular head of the sternomastoid. The internal jugular vein was divided between ligatures, and a very satisfactory exposure was thus obtained. A large pulsating swelling was seen in the floor of the wound, and this was separated with great care from the surrounding structures, to which it

between the swelling and the aorta, which was itself slightly enlarged. It was obviously due to this enlargement of the aortic arch that the whole of the structures were pushed upwards, and that access from above the clavicle could be obtained.

The carotid and vertebral arteries were next defined, but a large vessel arising from the anterior aspect of the swelling and running almost directly backwards occasioned some difficulty. This ultimately proved to be the subclavian artery, grossly displaced. Of other structures exposed, the vagus was seen passing downwards in front of the aneurysm, while the annulus of Vieussens could very clearly be seen encircling it.

FIG. 2.—Innominate artery in relation to veins.

FIG. 3.—Aneurysm of innominate artery as found at operation.

As digital compression on the common carotid artery did not cause any inconvenience to the patient, a wide ligature of kangaroo tendon was inserted and very gently tied so as just to obstruct the blood flow. A similar ligature was placed on the subclavian, which again caused no inconvenience, although the right pulse, of course, immediately stopped. These ligatures were tightened and loosened several times, and a period of fully half an hour was spent in ascertaining if either alone or together they produced any ill effect. When it had been satisfactorily demonstrated that they produced no symptoms whatever, a wide ligature of kangaroo tendon was placed on the innominate artery itself. The wall of the vessel was obviously fragile, and the ligature was therefore tied with great caution. As there was just room, a second ligature was then placed between it and the aorta, there being just sufficient more or less normal artery to carry the two. The ligature on the subclavian was now finally tied, but that on the carotid was removed, as it was thought that in this way the collateral circulation to the brain would be more easily established, while the complete absence of pulsation in the aneurysmal sac, which had now shrunk to comparatively small dimensions, suggested that this was not likely to prejudice the result of the operation. Finally, the sternomastoid was repaired and the wound closed, a small drainage tube being left in place for twenty-four hours.

The patient made an uninterrupted recovery without incident, and left the hospital four weeks after the operation.

The further course of the case is of some interest. The patient remained in perfect health until the end of December—that is to say, for seven months—when she had an attack suggesting a small cerebral haemorrhage. Following a very violent fit of sneezing she had a pricking sensation in the left hand, and some uncertainty of movement of the arms and legs. These were accompanied by a slight weakness in the left side of the face, a little difficulty in speaking, and a certain mental vagueness. This cleared up in the course of a few days, although the difficulty in speech persisted for a fortnight. The explanation of these symptoms, suggesting as they do a small haemorrhage on the right side of the brain, is by no means obvious, for one would have imagined that a haemorrhage in this region could scarcely follow ligature. They might have been due, of course, to a small embolus, but they resemble far more the symptoms which follow leakage from a small intracranial aneurysm. Fortunately no recurrence has taken place, and at the present time, nearly a year after the operation, the patient appears to be in perfect health.

FIG. 1.—Innominate artery in relation to sternum.

was adherent. A number of large vessels could be detected entering this swelling at various points, but owing to their gross displacement it was impossible at first to discover what they were. The swelling extended across the middle line of the neck, pushing the trachea backwards and to the left, and on freeing it in this region the innominate artery was found to enter it at about the middle line of the neck. The artery was very short, forming little more than a connexion

Literature on the Subject

The literature on the subject is not extensive, and it has been admirably collated on two occasions, by Sheen in 1905 and by Thompson in 1915. Ballance has described five personal cases, thus achieving a position which is unique, while Reid has recorded three cases in his review on all the aneurysms admitted to Johns Hopkins Hospital. I think it will be of interest to give a brief account of these articles, since each presents some important aspect of the subject.

Sheen's Case

Sheen¹ describes a case of aneurysm of the right subclavian, in which the innominate and right common carotid were tied at the primary operation, and two months later the subclavian was tied close to the aneurysm.

The patient was an old soldier, aged 46, who for six months had suffered from numbness and tingling of the right hand and arm, accompanied latterly by severe pain. Six days before admission he noticed a swelling above the right clavicle. He was a well-built man in good general health, with a typical pulsating swelling reaching 5 cm. above the right clavicle. The right radial pulse was only just perceptible, and the fingers of the right hand were bluish white. The heart and the other arteries appeared normal. At the end of two months' observation, during which the aneurysm increased in size, the operation was undertaken through a median incision extending from the cricoid cartilage to a point one inch below the sternal notch. The innominate was exposed after some dissection, and ligatured with stout floss silk to form a stay-knot of two ligatures. The carotid, which was now flaccid, was tied by a single silk ligature. Recovery was uneventful, but pulsation soon returned in the aneurysm. Two months later the subclavian was tied close to the aneurysm through an incision above the clavicle. There was no return of pulsation, and pain and tingling of the arm disappeared.

Sheen found thirty-six cases, including his own, of ligature of the innominate artery, of which, however, only eight recovered. As the cases dated back to 1818 it is evident that this very high mortality was largely due to sepsis and resulting haemorrhage. Only one patient, indeed (operated upon by Smyth of New Orleans), recovered in what may be termed the "pre-antiseptic" period of surgery. After the year 1871 sixteen cases were operated upon with nine deaths. Sheen concludes that the operation is reasonably safe in those cases in which the aneurysm is of a circumscribed character and in which the condition of the other arteries is good; that the carotid should be tied as well as the innominate, if possible at a previous operation; and that some cerebral lesion is the complication most to be feared.

Thompson's Case

Thompson² describes one case, and has collected fifty-two cases of ligature of the innominate artery from the literature.

His patient was a negro male, aged 46. Six weeks before admission a swelling appeared in the right arm-pit. Four days before admission the arm began to swell, and he had intense pain in the hand and wrist. The right axilla was occupied by a huge swelling, which extended upwards above the clavicle. The right arm and forearm were greatly swollen and oedematous with distended veins, and the radial pulse was imperceptible. Under local anaesthesia a transverse incision was made above the clavicle, dividing the sternomastoid, sternohyoid, and sternothyroid. The aneurysm was exposed, its sac blending with the scalenus anticus. On following the carotid downwards the innominate was exposed with ease, but the situation of the subclavian was such that ligature of this artery appeared to be too dangerous. The innominate itself was therefore tied with narrow linen tape, a stay-knot being formed. Pulsation in the aneurysm disappeared, and no cerebral symptoms followed. Pain and swelling in the arm remained, and a month after the opera-

tion a large axillary abscess was opened. A week later there was severe haemorrhage from the abscess cavity, which was stopped by packing. The patient died a month later without cerebral complications, and it was shown that the aneurysm was completely consolidated.

Thompson, as stated above, found in the literature fifty-two cases of ligature of the innominate artery, including the thirty-six described by Sheen, with a total of sixteen recoveries. He states that ligature of the carotid and the innominate together has a smaller mortality than ligature of the innominate alone. He has analysed a series of thirty-one cases operated upon between 1818 and 1915, with fifteen recoveries and sixteen deaths. It will be noticed that there was only one recovery before 1880: the patient was a man of 33, who was operated upon by Smyth of New Orleans in 1864 for a traumatic aneurysm occurring three months after an injury.

Ballance's Cases

Ballance³ describes five cases in three articles which he has devoted to the subject.

The first case, operated upon in 1902, was that of a soldier, aged 35, who for three months had suffered from loss of voice and swelling in the right side of the neck, with slight dysphagia. There was a large expansile swelling above the right clavicle slightly displacing the trachea. The swelling slowly increased in size. Under chloroform anaesthesia a median incision was made from the lower margin of the thyroid cartilage to the lower border of the manubrium. After a little blunt dissection with the finger the innominate artery was clearly felt. In order to obtain better access the manubrium was sawn through, and the upper portion split vertically. This did not give sufficient access, and a portion of the bone was therefore removed on each side. The innominate artery was then fully exposed and tied by four strands of goldbeater's skin ligature. The patient, however, developed a left hemiplegia and died the next day.

In the second case (1909) the patient, a man aged 35, had a pulsating swelling above the inner end of the clavicle. The wall of the aneurysm appeared to be very thin; but as it was extending rapidly operation was undertaken. The inner end of the left clavicle and the cartilage of the first and second ribs were divided and removed, with the left three-fourths of the manubrium. The exposure was good, but during the manipulation the aneurysm ruptured. The bleeding was immediately stopped by plugging the innominate with the finger. The artery was ligatured with kangaroo tendon, but the man died thirty hours later.

The third case (1912) was that of a man aged 43 with a pulsating swelling above the inner end of the right clavicle. Through a median incision the upper part of the manubrium was removed, giving a good exposure of the innominate, which was tied with a stay-knot. The patient recovered completely, with no complications.

The fourth case, operated upon in 1918, was that of a woman aged 60, who complained of a pulsating tumour above the right clavicle. It was about four inches in diameter, and extended into the superior mediastinum. As the x-ray photograph showed no deformity of the aorta it was determined to attempt ligature of the innominate. A vertical median incision was followed by a transverse one on a level of the upper border of the manubrium. The inner end of the left clavicle, the cartilage of the first left rib, and the left three-quarters of the manubrium were removed. A good exposure of the innominate was obtained, and it was ligatured with kangaroo tendon, forming a stay-knot. Following the operation the right arm was cold and partially paralysed, but it had completely recovered a month later. Pulsation in the aneurysm had ceased. The patient died two and a half years later from other causes, and necropsy revealed the complete success of the operation.

In the fifth case (1925), that of a man aged 55, there was a large pulsating mass extending high up on the right side of the neck and occupying the greater part of both anterior and posterior triangles. In spite of very considerable difficulty from the fixation of the tumour and its dimensions the innominate artery was tied successfully, and this was

followed by ligation of the common carotid and of the axillary arteries at later dates. The patient lived until 1933, and a full account of the case will be found in the *Lancet* for April 14th, 1934.

In his paper of January, 1922, Ballance mentions five other cases from recent literature with three recoveries, and one death from hemiplegia and one from haemorrhage at operation.

Reid⁴ reports that in 124 cases of aneurysm of various arteries admitted to Johns Hopkins Hospital, only three were true cases of innominate aneurysm, and, of these, two were operated upon. One patient died at operation, apparently from traction on the aorta, which would seem to be very dangerous. In one the innominate artery was tied and later the carotid, with improvement. The operation was performed by Halsted, and the patient lived six months, dying of pneumonia.

Other Records

Juckelson⁵ records a case in a man aged 30, following a punctured wound in the neck; he was treated by ligation of the innominate and extirpation of a portion of the sac, and was well five and a half years after the operation. Buchser⁶ gives a pathological report with a clinical history of an innominate aneurysm which perforated the trachea. His article includes a full bibliography of the German literature. Baldwin⁷ describes a case (1910) in which he ligatured the subclavian and the common carotid arteries in a woman aged 52, with an aneurysm of the innominate. She recovered completely and lived for eighteen years. The case is remarkable, since it has been generally held that in the case of innominate aneurysm distal ligation is not successful.

Lessnoi⁸ records a case of traumatic aneurysm of the right common carotid artery in a man of 35, treated by ligation of the innominate, with recovery. In the same article he describes eight other cases of traumatic aneurysm, so that the incidence in this region is obviously rare. Flint⁹ gives details of a case (1927) of a traumatic aneurysm of the innominate artery in a man of 37, following on a bullet wound received in 1918. Rapid growth of the aneurysm began in December, 1926, eight years after the injury, accompanied by severe dyspnoea and dysphagia. Proximal ligation of the innominate artery was carried out a month after the onset of symptoms, and this was followed by the opening up of a leaking aneurysmal sac, the turning out of the clot, and the suture of the open mouth of the subclavian artery. The patient made a good recovery. Cabot¹⁰ reports a case in which he ligatured the common carotid artery for an innominate aneurysm, but death occurred from pneumonia. McCarthy¹¹ discusses, at considerable length, the treatment of aneurysms by distal arterio-venous anastomosis, describing one successful case in which an aneurysm of the innominate was cured by anastomosis to the internal jugular vein.

Conclusions

It will be seen that ligation of the innominate artery for aneurysm is a well-established surgical procedure, in which the risks of the operation are entirely justifiable in view of the gravity of the condition. Technically the operation may be easy of achievement, or the difficulties from adhesions may render it impossible. Apart from the risk of haemorrhage at the time of operation, the two chief dangers to be feared are interference with the cerebral circulation and interference with the circulation in the arm. The latter does not appear to be as serious as might be imagined, probably because during the existence of the aneurysm a wide collateral circulation has opened up. The danger to the brain, however, must always remain a serious one, and there would seem to be

no means of discovering the extent of the risk in any particular case.

I am convinced that the method adopted, of operating under local anaesthesia and of applying tentative ligatures to the arteries, is a sound one. General anaesthesia involves a disturbance to the circulation, which cannot be anything but inimical to the interests of the patient, while it precludes entirely the very important information, which a conscious patient can give, as to the effects of occluding the circulation of a large vessel.

HYPERTONIC RECTAL SALINE FOR INTRACRANIAL INJURY IN THE NEWBORN

BY

ALAN MONCRIEFF, M.D., F.R.C.P.

PHYSICIAN TO THE CHILDREN'S DEPARTMENT, MIDDLESEX HOSPITAL;
PHYSICIAN FOR DISEASES OF CHILDREN, BOLINGBROKE
HOSPITAL; ASSISTANT PAEDIATRICIAN, QUEEN
CHARLOTTE'S MATERNITY HOSPITAL

J. N. Cruickshank, in his study¹ of 800 cases of death in the newborn, wrote: "The present writer believes that increased intracranial pressure is a factor of first importance in the production of a large proportion of cases of neo-natal death." Modern investigations have shown how intracranial pressure can be reduced by the introduction of hypertonic salt solutions intravenously or into the alimentary canal. The present communication is an account of the practical application of these experimental findings in an effort to save a certain number of newborn babies who would otherwise die.

It is generally agreed that, as a result of the birth process, the contents of the baby's skull may exhibit haemorrhage (gross or microscopical), oedema and congestion, or contusion. Cruickshank's studies throw doubt upon the supposed frequency of small areas of haemorrhage, and, in his view, haemorrhage into the substance of the brain does not occur, except in unusual circumstances. He believes that the clinical effects often attributed to haemorrhage are due really to congestion and oedema, leading to anoxaemia of the medullary centres. In the post-mortem records of Cruickshank's monograph, oedema of the brain and meninges was a very constant finding, especially in those cases marked in life by respiratory failure. It is not maintained that hypertonic rectal saline can do anything for those cases in which meningeal or cerebral haemorrhage has occurred, but in view of Cruickshank's findings as regards the latter alternative I believe it should always be used, even if the clinical diagnosis between oedema and haemorrhage cannot be made.

Pathology of Increased Intracranial Pressure

The clinical features of this condition in the newborn may be briefly sketched against the pathogenic background referred to above.

The labour has usually been somewhat difficult, with a prolonged second stage. Occipito-posterior presentations,

forceps deliveries, and other departures from normal have frequently occurred. Premature babies, despite the smaller size of the skull, are well known to be more liable to intracranial complications. The baby may exhibit respiratory difficulties from the onset, but more usually, in the cases I have treated successfully, the condition following delivery has been fairly good, and the symptoms have developed gradually in the first two or three days of life. A refusal to feed, with deepening somnolence, often alternating with periods of restlessness and crying, is usually the first manifestation. Recurrent vomiting may occur, the fontanelle is found to be bulging, and frequent twitchings of the facial muscles and limbs are observed. Failure of respiration with attacks of cyanosis is a very constant feature.

I believe that the problem here to be solved differs in no essential from that presented by head injuries in adults and older children. In the same way, a rising intracranial pressure threatens life, and the investigations largely inspired by Cushing in relation to intracranial surgery have an important application in the neo-natal period. Two out of the many contributions on the subject of hypertonic salt solutions and the lowering of intracranial pressure may be briefly summarized to illustrate the experimental justification for the methods of treatment here indicated.

Foley and Putnam² quote Cushing to the effect that people with headaches often secure relief by thorough intestinal evacuation, especially when this is accomplished by salines. In their experiments the introduction of a 30 per cent. sodium chloride solution into the rectum in animals produced a steady and great drop in the pressure of the cerebro-spinal fluid, the systemic blood pressure remaining unaffected. Even with a 10 per cent. solution they recorded a notable fall in the pressure of the cerebro-spinal fluid, which was maintained for some hours. About 35 c.cm. were used for a cat, and retained in the rectum as long as possible. Cushing and Foley³ point out that while reduction in intracranial pressure can be produced by the intravenous injection of hypertonic saline, this is to a certain extent undesirable because of effects upon the pulse, respiration, and blood pressure. (From the point of view of practical midwifery, intravenous injections for the newborn present gross difficulties.) They found that even small doses (5 c.cm.) of a 2 per cent. sodium chloride solution into the alimentary canal of the cat below the stomach (that is, duodenum or rectum) produce a definite effect in lowering the intracranial pressure, and they obtained confirmation of the effects of hypertonic salt solutions in patients with brain tumours after operations for decompression.

Danly⁴ and Jefferson⁵ have criticized the use of hypertonic salt solutions in the treatment of head injuries, but it is agreed by the latter that, properly used, this method of treatment has its place. The term "dehydration" is possibly responsible for criticism in reference to such solutions, and, certainly in the newborn, any attempt at producing dehydration is to be strongly deprecated. It might be urged that more prompt results may be obtained by the use of lumbar puncture, but the method to be described here is much easier of application, is less disturbing to the infant, and can be repeated as often as is required without any difficulty, while offering less risk of further damage to the brain.

Observations with the Method

The present method has been evolved over a period of nearly twelve months, and about twenty babies in hospital and private practice have been treated, mostly with highly successful results. I have not attempted to compare mortality rates for this and other methods of treatment, because, fundamentally, it is difficult to decide whether babies who survive would have died had they not been so treated. I can only record that obstetricians, resident officers, midwives, and nurses have been impressed with the results. A bulging fontanelle becoming normal, a comatose baby coming out of coma and taking feeds normally, and the cessation of twitching and of cyanotic attacks are some of the effects which have been observed.

Technique

The method now in use consists of the introduction of two to three ounces of 10 per cent. saline into the rectum of the newborn babe, as soon as any of the symptoms mentioned above appear.* The nurse is instructed to do this slowly, with the baby in the cot and with the minimum of disturbance, and to hold the buttocks together to get as long a retention as possible. Strong solutions are very quickly returned, and weaker solutions are not so effective, although an early case treated with only 2 per cent. saline made such a good recovery that it afforded encouragement to proceed with the method. The injections can be repeated at four-hourly or longer intervals, according to the improvement obtained. The method is wholly free from harm, and can be carried out by nurses undertaking domiciliary midwifery. "Ten times normal saline" is a convenient way of describing the strength of the solution used (ten teaspoonfuls of salt to the pint of water, or one teaspoonful in two ounces to make only the required quantity).

Other ancillary forms of treatment must not be neglected. As with head injuries in later life, absolute rest is of fundamental importance. Such babies must not be lifted out of bed for any purpose. Feeding must be carried out with breast milk expressed from the mother (or from other sources, if possible, in the early days). If the baby cannot suck, spoon-feeding may be tried, or, if this fails, an oesophageal tube. Small doses of chloral are valuable (1½ grain) if any restlessness or twitching is present. Five per cent. carbon dioxide in oxygen through a nasal catheter is of great value for failure of respiration, and if there is the slightest suggestion of intracranial haemorrhage (indicated by the rapid onset of symptoms shortly after delivery) I believe it is sound to withdraw 10 c.cm. of blood from the mother and inject this intramuscularly into the baby.

In some instances a certain amount of spasticity is found to be present in the first few weeks after recovery. I was at first depressed by this, thinking that the method was possibly saving a certain number of infants who would have been better spared from a life of paralysis and imbecility. Longer experience has indicated that stiffness of the muscles usually wears off by 3 months of age. I do not think the method can possibly influence the survival of cases with structural damage to the brain. On the other hand, since oedema and congestion of the brain are temporary conditions which will disappear in the course of a few days if only the infant's life can be preserved, the use of hypertonic saline appears to offer a chance of reducing the risks of increased intracranial pressure which Cruickshank, on the basis of his wide pathological experience, believes to be of such great importance in the problem of neo-natal death.

* Since this was written it has been decided to use the method prophylactically. A baby after a difficult delivery is given hypertonic saline almost immediately.

The National Physical Laboratory has issued a new edition of its pamphlet "Tests on Volumetric Glassware." No fundamental changes have been made from the preceding edition, but several points have been dealt with in more detail—for example, the testing of burette tops and permissible schemes of subdivision of scales on graduated glassware. Copies of the pamphlet may be obtained free of charge on application to the Director, National Physical Laboratory, Teddington, Middlesex.

OBSERVATIONS ON EXPERIMENTAL SHOCK

BY

R. L. HOLT, F.R.C.S.

AND

A. D. MACDONALD, M.A., M.B., CH.B.

(From the Department of Pharmacology, University of Manchester)

Whilst the theory of traumatic toxæmia has been accepted in this country as providing the most reasonable explanation of the condition recognized by surgeons as secondary shock, a body of experimental research, which seems to discount this theory completely, has been produced in America during the past few years by a number of workers.¹⁻⁴ The still earlier theories have been generally discarded, since they fail to account for the diminution in the volume of the circulating blood, a diminution which Keith¹ emphasized and which is now generally admitted to be the outstanding feature of this type of shock. The theory of traumatic toxæmia arose from the observations of the Special Investigation Committee appointed by the Medical Research Council in 1917. Its reports were published officially,² and, later, Cannon summarized the work in his monograph,³ in which he also shows that the other theories of the ætiology of shock are untenable.

Shock was usually produced by traumatizing one of the posterior extremities of cats. The low blood pressure which resulted from such trauma was found to occur whether or not the nerves to the limb or the spinal cord had been severed prior to the damage. The amount of swelling due to loss of plasma or blood into the traumatized area was not believed to be sufficient in itself to account for the fall in the blood pressure. Further, it was found that by clamping the main artery and vein to the limb before trauma was applied collapse of the circulation was delayed until the clamps were removed. It was assumed that a depressor substance was liberated in the damaged tissues and that the fall in blood pressure was due to the absorption of this substance into the general circulation, on which it acted.

The Histamine Theory

About the same time, Dale and Laidlaw⁴ described a shock-like condition produced in animals by the injection of histamine. This condition bore so close a resemblance to the shock produced by muscle trauma that it seemed reasonable to regard the two kinds of shock as closely related. Although the pure chemical substance has been separated from many tissues of the body this histamine theory has never been substantiated by the demonstration of a depressor or shock-inducing substance in the blood of the shocked animal. Furthermore, it is quite evident, as Smith⁵ points out,

"that the failure to produce shock by crushing the muscles of a limb, the main vessels of which have been clamped, is susceptible of an interpretation other than the prevention of the hypothetical capillary poison from reaching the general circulation. It might well be supposed that shock does not occur under these conditions because there is no actual loss of blood, whereas upon removal of the clamps shock does occur because of the extravasation of blood and transudation of plasma into the lacerated tissues."

Smith showed that when blood withdrawn from a branch of the distal end of the clamped femoral vein, after the muscles of the limb had been thoroughly crushed, was returned to the circulation there was not the slightest evidence for the presence of any depressor substance in this blood. On the contrary, the blood pressure was raised, being restored to the pre-bleeding level. The transfer of such blood to another animal which had been bled but not otherwise traumatized also raised the recipient's blood pressure, and never yielded any evidence

of containing histamine-like substances. If, however, histamine was injected intra-arterially into the limb the blood collected later from the clamped vein was easily shown to be depressor to the circulation of either the shocked animal or a bled recipient. Some mechanism other than the liberation of a histamine-like substance must then be responsible for the production of shock.

The Local Loss of Blood

Blalock⁶ repeated the experiments of Cannon and Bayliss⁷ on dogs. He found that trauma to the leg never reduced the blood pressure to a shock level without causing the loss of enough blood and plasma into the traumatized area to account for the fall. These results were opposed to the conclusions of Cannon and Bayliss, who stated: "In no case, however, was there sufficient bleeding into the wounds to account, by itself alone, for the effects observed." But Cannon and Bayliss determined the local loss of blood by weighing the extremities, traumatized and control, after amputation by symmetrical cuts across the upper ends of the thighs. Blalock soon discovered that trauma to a thigh results in extravasation into the loose tissues of the groin and flank. To include this in his comparative weighings he separated the hindquarters butcher-fashion, cutting across the body in the mid-abdominal region and splitting the lower part of the vertebral column. The difference in the weights of the limbs thus amputated in all experiments in which a low blood pressure was produced by trauma to one limb amounted to at least 4 per cent. of the body weight, or about half of the total calculated blood (taking the blood as one-thirteenth of the body weight). This work supplies such an impressive body of evidence and has received so little attention in this country that we decided to repeat, with such differences in technique as seemed advisable, the fundamental experiments of Smith⁵ and Blalock.⁶

EXPERIMENTS A

Depressor Substances in Blood from Damaged Limb

Dogs were anaesthetized with sodium barbitone (0.3 gram per kilo intravenously). Records of blood pressure and respiration were taken in the usual way: blood pressure, by means of a cannula in a carotid artery, connected to a mercury manometer; and respiration, by a tambour applied to the lower ribs. Shock was induced by striking the thigh muscles with the flat side of a 2 lb. hammer, applied so that neither the skin nor the bone was broken. For transfusion experiments clotting was prevented by the intravenous injection of chlorazol-fast pink (Boots), as recommended by Huggett,⁸ in a dosage of 200 mg. per kilo body weight. By inserting a three-way cannula into the common iliac vein it was possible to withdraw either the whole or part of the blood returning from the experimental limb during or after the trauma. This gave no trouble, probably because of the efficiency of the anticoagulant. In the light of Blalock's work it is obviously desirable to draw samples from and to clamp the common iliac vessels rather than the femorals, as practised by Smith.

Sixty c.cm. of blood collected during the latter part of a shock-producing trauma were reinjected as soon as the blood pressure became steady. This raised the blood pressure, although the sample was taken during a steep fall, when the likelihood of a spread of any depressor substance present was at its greatest. In no experiment of this kind, in which we have collected and reinjected blood from a traumatized limb, have we found any evidence for the presence in that blood of any histamine-like substance, taking the blood either during the trauma or at any interval afterwards. And the same conclusion is arrived at if the blood is transferred to another animal in which no trauma has been induced and which, with its higher blood pressure, is probably more sensitive to the action of depressor substances. If after clipping the vein we injected 1 mg. of histamine into the iliac artery of that leg and collected a small blood sample (5 to 10 c.cm.) from the vein even ten minutes later, such blood on reinjection produced a typical histamine response—a sharp fall in pressure with recovery in a few minutes.

These results are shown in the kymographic record here reproduced, and confirm Smith's claim that "direct methods have failed to demonstrate a depressor substance in the blood of the shocked animal."⁵

EXPERIMENTS B

Local Loss of Blood and Plasma

In this series of animals the same recording methods and the same technique for inducing anaesthesia and shock were used as in the previous experiment. When the blood pressure seemed to be established at a shock level the hindquarters were divided as recommended by Blalock, and weighed. The

figures for ten dogs are set out in the accompanying table, which shows the blood pressure changes, the loss of blood and plasma into the traumatized area (indicated by the difference in weight between the limbs), and the proportion of the circulating blood which this loss represents. Great care was taken in dividing and weighing the limbs to ensure the reliability of these figures. The average percentage of blood volume lost into the traumatized area is calculated at 57 per cent., an ample confirmation of the observations of Blalock,

who claims a corresponding figure of 50 per cent., whereas Cannon,¹⁸ amputating at a much lower level, found that the difference in weight only amounted to 11 per cent. of the blood volume. In a series of cats the corresponding figure was 43 per cent. Although lower than in dogs, this fluid loss is quite sufficient in itself to account for the collapse of the blood pressure, and makes it unnecessary to assume the absorption and general action of any histamine-like substance.

The nature of the fluid which produces the marked increase in the weight of the traumatized limb has been investigated by Blalock.¹⁹ He found that the local gain in weight was

Female, 9½ kg. Na barbitone, 2.85 grams, as anaesthetic; chlorazol-fast pink, 2 grams, as anticoagulant. (A) Effect of trauma on blood pressure: reduced from 105 to 60 mm. Hg; 60 c.cm. of blood collected from the iliac vein of the traumatized leg towards the end of trauma. (B) The return of this blood raised the blood pressure from 60 to 90 mm. Hg. Within half an hour the pressure had again fallen to 60 mm. Hg. (C) The iliac vein was clamped and 1 mg. histamine injected into the left common iliac artery. (D) Twelve minutes later 6 c.cm. blood was collected from the clamped vein and injected intravenously in the other leg, producing a brief fall in blood pressure because of the histamine present.

EXPERIMENTS C

The Initial Fall in Blood Pressure

In our earlier experiments we were surprised at the amount of trauma which was necessary to keep the blood pressure

at a shock level. If no attempt was made to sustain the normal body temperature shock was maintained much more readily. We found that in healthy, well-nourished animals which were kept warm the blood pressure could often be brought down to a shock level by slight trauma, but on cessation of this the blood pressure tended to rise rapidly to normal. This fall in blood pressure came on so quickly as to suggest that it was of neurogenic origin.

It has been shown by several workers that denervation of a limb, even if it includes sympathectomy or transection of the cord,² does not prevent the development of shock following trauma. These results were obtained from experiments in which shock was maintained. We determined to investigate the cause of the initial fall in blood pressure, believing that it might produce further evidence of the changes taking place in the traumatized tissues. The animals were anesthetized and records taken as in Experiments A and B. We found that the fall in blood pressure after mild trauma occurred: (a) when all nerve impulses from the limb had been cut off by means of a spinal anaesthetic, the efficiency of which was tested by faradizing the central end of the sciatic nerve; and (b) when the common iliac vein was occluded, preventing the passage of blood from the traumatized tissues into the general circulation. The fall in blood pressure was prevented by occluding the iliac artery.

These findings suggested that even the initial fall in blood pressure is the result of a local change, presumably an opening up of the large vascular bed provided by the thigh muscles. Whether or not such a change is produced by the local action of a histamine-like substance as a result of the tissue injury we cannot say, but certainly, in our experiments, there is no evidence of the passage of such a substance into the general circulation.

Discussion

The old division of shock into primary and secondary types is misleading, since it does not take into account the pathological features of the two conditions. Primary shock is most reasonably explained on the basis of a disturbance of the nervous system. It is similar in origin to the fainting which not infrequently accompanies severe injuries. This variety of shock results from a reflex inhibition of the heart and a reflex relaxation of the vascular tone throughout the body. In the absence of gross injury to the nervous system there is a strong tendency to recover rapidly from this type of shock, for which the term "neurogenic" has been suggested. Secondary shock may develop several hours after injury, or in the presence of severe injuries it may follow so closely upon the primary shock that no temporary

Experiment	Dog's Weight in Kilos	Initial Blood Pressure, mm. Hg	Shocked Blood Pressure, mm. Hg	Weight of Traumatized Limb in Grams	Weight of Control Limb in Grams	Difference in Limb Weights Calculated as Percentage of Animal's Total Blood

10	9½	165	60	1,500	1,260	33

Average percentage of blood volume lost in traumatized area = 57 per cent

due to the transudation of plasma rather than of whole blood, since the haemoglobin content of the fluid expressed from the traumatized limb was only 30 per cent. of that obtained from the control. This finding explains the result generally reported that the blood in traumatic shock is concentrated. We have attempted to follow the blood changes in these experiments by hourly cell counts and haemoglobin estimations. It was not unusual for the cell count and haemoglobin concentration to be increased by 25 per cent., or even more, as shock

recovery is demonstrable. Any satisfactory explanation of this type of shock, for which the term "haemogenic" has been suggested, must account for the diminution of the blood volume and the concentration of the blood which form the essential pathological features of this condition.

According to recent American work, which has been confirmed by us, the lowered blood volume is due to the loss of blood and plasma into the traumatized area. The immediate onset of this type of shock is characterized by a local vaso-dilatation of the vessels in the injured area, which is accompanied by an increased permeability of the vessel walls and a transudation of plasma into the tissue spaces. This is naturally accompanied in traumatic cases by some extravasation of blood from ruptured vessels, but, except in cases of severe haemorrhage, the loss of plasma is relatively greater than the loss of whole blood.¹⁰ In this way some concentration of the corpuscles in the circulating blood is accounted for. The cause of the increased permeability of the capillaries in the traumatized area is not definitely known. It is probably the result of a substance which is freed locally by the injured tissues, but no clue as to its nature is obtainable, since there is no evidence of its absorption into the general circulation.

This theory of secondary shock stresses the fact, which is supported by experimental evidence, that the lowered blood pressure and blood volume so typical of this condition are due primarily to local factors and not to a general increase in capillary permeability, as postulated by Cannon and Bayliss. This local factor, though the most important, is not working alone to bring about a state of shock, for, unless the blood volume is diminished so greatly as to cause death within a short time, there is a strong natural tendency to restore the blood volume to its normal level by drawing on the fluid reserves of the body. That such a change takes place was indicated in some of our experiments by the steady rise in the blood pressure and the accompanying dilution of the previously concentrated blood which took place after the cessation of trauma. The local factor may therefore be regarded as the initiating factor, but in order to maintain the state of shock others, which may be called sustaining factors, must be present. The loss of blood which frequently accompanies injuries directly lowers the blood volume. Sweating (common in severe shock), vomiting, and, under active service conditions, the prolonged lack of food and water reduce the reserves of body fluids which are necessary to restore the blood volume. Cold and exposure are also potent influences. In the presence of one or more of these sustaining factors the blood pressure is maintained at a level lower than is necessary to ensure an efficient circulation. Anoxaemia of the tissues, a lowered metabolic rate, increased permeability of the capillaries, and an increased viscosity of the blood are among the important changes which result from the low blood pressure. Cannon³ sums up the situation by saying: "A series of vicious circles may thus be started which, if not interrupted, lead to a still further aggravation of the already existent abnormal state, and which account for the progressive nature of fatal shock."

Clinical Considerations

The experimental work described in this paper has been concerned with trauma applied to one of the posterior extremities of anaesthetized animals, and any clinical application must therefore be made with some reserve. In civil practice severe burns and accidents are among the commoner causes of secondary shock. We believe that our experimental work is sufficiently similar to allow of comparison with the shock found in accidents, for

secondary shock is characteristically observed in connexion with extensive damage to muscles or with multiple wounds in which the sum of the damage is equivalent to considerable injury in one region. The secondary shock associated with severe burns has been somewhat overlooked as a result of the marked improvement which has followed the adoption of the tannic acid treatment. Underhill¹¹ claimed that the shock associated with burns was due to the marked concentration of the blood, and obtained excellent results from simply forcing fluids. Blalock¹² extended his experiments to the production of burns to wide areas of the body surface of dogs. Here again he found in the burnt and surrounding tissues an excess of fluid, akin to plasma, equivalent in amount to 40 or 50 per cent. of the total blood volume. This factor of loss of fluid after burns may be even more important in the human being than in the dog, since there is frequently a copious exudation from the injured skin in man which is not seen in dogs. It seems probable that the beneficial effect of tannic acid is largely dependent on the prevention of fluid loss as well as on lessening the absorption of toxins. Results obtained in the shock which results from intestinal manipulation¹³ also stress the importance of the local factor in producing secondary shock. In fact the present outlook would seem to relegate to a secondary position the toxic factors which have been regarded for the past fifteen years as of primary importance in the production of secondary shock.

The present theory of the pathology calls for no radical change in the treatment of secondary shock. Operations under ether, chloroform, or spinal anaesthesia, which all tend to produce in the presence of a low blood volume a pronounced fall in blood pressure, are contraindicated until adequate measures have been taken to restore the blood volume to normal limits. In secondary shock the restoration of the blood volume by the slow intravenous injection of compatible blood, or, failing that, of a gum-saline solution, the application of heat to the body, and the alleviation of pain and restlessness still form the cardinal features of the therapy, but further work on the treatment of shock is now in progress.

Summary

The evidence against the acceptance of the "Traumatic toxæmia" or histamine theory of secondary shock is reviewed and accepted, since: (1) we have been unable to demonstrate the presence of any depressor substance in the blood from a traumatized area; and (2) in no experiment was the blood pressure reduced to a shock level without there being a loss of plasma and blood into the injured tissues, sufficient in itself to account for the effects observed.

A NEW PRINCIPLE IN ETHYL CHLORIDE ANAESTHESIA FOR ORAL SURGERY

BY

R. BLAIR GOULD, M.B., CH.B.

CONSULTING ANAESTHETIST TO THE LONDON COUNTY COUNCIL;
ANAESTHETIST, GOLDEN SQUARE THROAT, NOSE, AND EAR
HOSPITAL, ROYAL DENTAL HOSPITAL, ETC.

The technique of this method of anaesthesia was elaborated by Dr. Max Borchardt of Berlin. It has been in use on the Continent during the past two years, during which time many hundreds of cases have been reported.¹ The only reference to it in the English literature which I have been able to trace is a short article by H. H. Tomlinson of Liverpool.² The method introduces such a complete innovation in ethyl chloride anaesthesia that it well merits a more detailed description.

The Somnator

The apparatus shown in Fig. 1 is known as the "sommator," and is easily portable. It consists of two parts: a metal mouthpiece (see lower part of the figure), to the inside of which is attached a bag of a highly absorbent material, readily permeable to air; and a nosepiece, which is made to fit into the mouthpiece, and consists of a wire frame over which is stretched a bag of the same fabric. The mouthpiece and nosepiece are attached to each other by rubber bands, by which they are also attached to two metal loops designed to fit over the ears. A further rubber band passes from one ear loop to the other behind the occiput in order to retain the apparatus in position. The fabrics are easily interchangeable, and the whole apparatus may be sterilized by boiling.

Administration of Anaesthetic

The technique of administration is as follows. The nosepiece is placed inside the mouthpiece, and the patient is asked to hold the latter between the teeth or lips, a dental prop having previously been inserted, if desired. The ear loops are placed in position, and the

patient is receiving abundant supplies of air through the nose, and the anaesthetic is diluted by the air passing through the mouthpiece. This is a very important fact, as inhibition of respiration is easily brought about by too concentrated a vapour.

As the anaesthesia progresses the nosepiece is lifted out of the mouthpiece and inverted over the nose (Fig. 3). Ethyl chloride is now sprayed on to both fabrics, the concentration being increased until the third stage of anaesthesia is reached. The mouthpiece is then lifted out of the mouth and inverted over the nosepiece (Fig. 4). The surgeon now commences his work, and during the operation the mask remains over the patient's nose, such quantities of ethyl chloride being sprayed on to it as may be necessary.

FIG. 1.

Advantages of the Method

It will readily be seen that this method is a great advance in the technique of ethyl chloride anaesthesia, and that it introduces such an element of safety that it is likely to replace present methods in suitable cases. In the present method ethyl chloride is administered by means of a face-mask or rebreathing bag until the patient is judged to be so deeply under its influence that the anaesthesia will last throughout the course of the operation. Using the sommator this no longer applies. The surgeon can commence as soon as the patient has become anaesthetized, and the

subsequent depth of anaesthesia is entirely under the control of the anaesthetist. Dangerous dosage or concentration of the anaesthetic are avoided, and by reason of the large quantity of air which the patient receives throughout the anaesthetic the colour remains pink. These are most important factors in contributing to the safety of the anaesthetic.

In my experience of over a hundred cases it has proved equally satisfactory for children and adults, and has given anaesthesia of four minutes' duration without ill effect. It is in my opinion as great an advance on present methods as nasal nitrous oxide is an advance over the old "straight" gas. In cases where it is not desired to pack off the mouth, or where it is important to eliminate

FIG. 2.

FIG. 3.

FIG. 4.

occipital rubber band attached (Fig. 2). The apparatus is now self-retaining, and the anaesthetist's hands are free to hold the jaw and steady the head. A few drops of ethyl chloride are sprayed on to the fabric. It is important not to spray more than 0.5 c.cm. of anaesthetic on to the fabric at once, so that the possibility of liquid ethyl chloride reaching the patient's face is avoided. The patient is told to breathe deeply. During this stage the

mouth-breathing, the anaesthetic may be commenced with the apparatus over the nose, as shown in Fig. 4, the mouth being covered with an obturator during induction. The slight disadvantage of a prolonged induction due to the dilution of the anaesthetic vapour by air can easily be eliminated by means of a towel placed over the apparatus. In general anaesthetics, where open ether is preceded by an ethyl chloride induction, the use of this

method entirely eliminates the fear which is engendered in a patient by the face-mask. The induction is pleasant and almost imperceptible to the patient, and after induction the apparatus is easily removed and the usual mask substituted.

For use with the somnator there has been elaborated a new type of ethyl chloride, containing 15 per cent. of added constituents (valerian, camomile, peppermint, and alcohol) by which the boiling point has been raised and freezing of the ethyl chloride on the fabric thus prevented. This latter constitutes one of the disadvantages of ordinary ethyl chloride, as when freezing occurs the concentration can no longer be controlled. It is also claimed that the added valerian reduces excitement and after-vomiting, a claim which appears to be substantiated in my series of cases. Out of thirty-four cases in which the apparatus was used with ordinary ethyl chloride eleven (32.3 per cent.) vomited, but in thirty-six cases where the special ethyl chloride was used only two (6.6 per cent.) vomited. This ethyl chloride has, however, the disadvantage that induction appears to be unduly prolonged, and its anaesthetic action is somewhat weaker.

I am much indebted to Mr. F. St. J. Steadman, the senior dental surgeon to the West London Hospital, and dental surgeon to the Royal Dental Hospital of London, for kind permission to use the method at his clinics. The apparatus is marketed in England by Messrs. Cottrell and Co., 15, Charlotte Street, London, W.1.

Clinical Memoranda

AN UNUSUAL CASE OF DIPHTHERIA

Cases of diphtheria of the vulva are noted in the literature¹ of this disease, but the following case presents circumstances unusual enough to merit a record.

A girl of 7 years was brought to Dr. B. R. Nisbet, medical officer of health for Kilmarnock, on November 12th, 1933, suffering from a purulent vaginal discharge, which had become evident the previous day. Although smears showed the absence of gonococci, the clinical symptoms were so strongly suggestive of vulvo-vaginitis that he sent the child on November 15th to the venereal diseases ward of Heathfield Hospital, Ayr, for observation and treatment.

On admission, the patient was noted to have a purulent vaginal discharge with redness of the vulva and several small circular excoriations of the labia majora. No membrane was visible. The day following admission the patient complained of a sore throat and was feverish, and inspection of the fauces revealed typical diphtheritic membrane on both tonsils. A direct examination of the swab clinched the diagnosis, and 16,000 units of diphtheria antitoxin were given at once.

Smears of the vaginal discharge similarly examined showed pus cells, Gram-positive bacilli, and mixed coccal forms, but no gonococci. Cultures of the throat and vaginal secretion both showed typical Klebs-Loeffler bacilli, and the culture of vaginal pus was sent to Glasgow Public Health Laboratory for a further test of the organisms. These were reported virulent in the guinea-pig.

With rest and the ordinary toilet of the vulva, the patient recovered and was discharged well on January 27th, 1934, the undue length of her stay in hospital being on account of a persistent slight cardiac irregularity in convalescence.

Associated Features.—Immediately faucial diphtheria was diagnosed Dr. Nisbet was informed, and he has since supplied me with the following interesting data. On November 16th, 1933, a further case of faucial diphtheria was notified from a house in the same block of the tenement wherein the girl resided, and was removed to hospital. On December 1st a

brother of the patient was similarly dealt with. On December 5th another brother of the patient was found to have a positive nasal culture, and still another case of diphtheria was discovered in the same tenement.

This case appears to have been one of primary vulval diphtheria with secondary infection of the throat. I am indebted to Dr. Nisbet for his assistance in amplifying the report.

OBSTRUCTION OF THE OESOPHAGUS BY THE BEARD

The novelty of this case of oesophageal obstruction is, I think, worthy of record.

Some two years ago a man called upon me in an emergency with the history that some food had lodged in his throat, preventing all further attempts at swallowing. His wife, who accompanied him, was necessarily the spokeswoman, because it transpired that the patient had been subjected to complete laryngectomy (for carcinoma) some eighteen months previously in London. The man had made a splendid recovery, and breathed normally through the stump of his trachea at the root of the neck.

Indirect inspection of his funnel-shaped deep pharynx showed a bolus of meat, which I removed. As the swallowing was not relieved, a further examination revealed another mass of meat, which I proceeded to pull up. During this act, to the amazement of both the patient's wife and myself, the meat was accompanied by a thick, twisted, slimy tuft of long black hairs, which we both hauled up for at least twelve inches. By further vigorous (and rather painful) traction it eventually came away in our hands, and the small remains slipped back into the man's throat. After this the act of swallowing was quite normal.

For a short time it was difficult to account for such an unusual occurrence, but it soon dawned on me that this patient had had a plastic operation performed on the front of his neck to close a pharyngeal fistula subsequent to laryngectomy, with the result that he was now growing part of his beard in the gullet.

I do not know the subsequent history of the case, but believe that x-ray therapy was suggested as a depilatory. The alternative, of course, would be periodical clipping of the hairs through an endoscope.

Liverpool.

JOHN ROBERTS, F.R.C.S.

DUODENAL ULCER IN A 10-YEAR-OLD CHILD

Duodenal ulcer in a child of this age is a comparatively rare condition. The following is the record of a recent case.

The patient, a girl aged 10, was seen in the out-patient department, and gave the following history. Off and on for the past six months she had had pain in the region of the stomach. The pain was present when she awoke in the morning, was relieved by a hot drink, and, at times, persisted throughout the morning. The school teacher allowed her to go home for a hot drink when the pain was severe. The bowels were regular, and there was no vomiting. On examination there was tenderness under the right costal margin, and opaque meal examination showed well-marked seven-hour gastric retention and an absence of any duodenal filling. Unfortunately a test meal was not given.

The child was admitted into hospital without any definite diagnosis having been made. The pyloro-duodenal region, the gall-bladder, and the appendix were under suspicion; we had also to bear in mind the possibility of some form of abdominal tuberculosis. Under avertin and local anaesthesia the abdomen was opened through a right paramedian incision and the following pathology disclosed: gall-bladder normal; mobile caecum; appendix normal externally, but the mucous membrane of the tip was bluish red; large duodenal ulcer, palpable and visible in the first part of the duodenum. The hepatic surface of the duodenum was

¹ Medical Research Council *Diphtheria* (1923), p. 230.

the portion involved, and its peritoneum showed numerous petechiae. The involved bowel was hard. The appendix was removed, and a posterior gastro-enterostomy, with a vertical stoma extending from the incisura angularis to the great curve, was performed. This was on February 5th, 1934, and the child has had complete freedom from her dyspepsia up to the present time. Convalescence was uneventful.

REMARKS

Berglund¹ found only fourteen duodenal ulcers in 1,323 post-mortem examinations in children under 13. Dietrich,² in 8,534 post-mortem examinations, found six cases of duodenal ulcer in children under 10. In the Mayo Clinic only two out of 8,360 cases of duodenal ulcer were in children. Kennedy³ reports on five cases of duodenal ulcer in children, and recognizes four distinct groups according to age.

Group 1: Ulcer in the newly born, which makes its presence known by melæna neonatorum. Group 2: Ulcers in children from a few weeks to the end of the first year. These are acute, and are probably of an infectious nature. Group 3: Ulcers in children from 1 to 9 years. These are chronic, and frequently fail to give rise to any suggestive symptoms. Group 4: Ulcers in children from 9 upwards. These give symptoms similar to adult duodenal ulcer, and may be treated in a similar manner.

Our case would appear to fall into Group 4, since it gave rise to typical dyspeptic symptoms and responded well to gastro-enterostomy.

One would hope in a child of 10 to obtain some light on the aetiology of duodenal ulcer. An investigation of the literature shows that quite a number of duodenal ulcers in children are associated with tuberculous disease of the lungs. For example, Gray⁴ relates the death of a 5-year-old child from hæmorrhage from a duodenal ulcer, and the post-mortem examination revealed pleurisy with effusion. Murchison⁵ describes a duodenal ulcer in a child with tuberculous deposits in the lungs. In Berglund's post-mortem material six of the nineteen with duodenal and gastric ulcers had tuberculous meningitis or syphilis. Our case shows a normal chest radiogram, a negative Wassermann reaction, and no evidence of tuberculous disease. It has been suggested that a mobile caecum or pathology of the appendix might be a factor in the aetiology of duodenal ulcer, and we must record that this case had a caecum which could be withdrawn easily through a right paramedian incision, and had an appendix which showed slight pathological changes at its tip. One hesitates to stress this relation in view of the very large number of deformed and diseased appendices and mobile caeca which exist in the presence of a normal duodenum.

Finally, we would like to emphasize the importance, in a child, of seven-hour gastric retention, revealed by x-ray examination of the opaque meal. For many years we have been exploring abdomens which give this sign, and in the majority of cases it leads the surgeon into suitable surgical pathology. Appendicular deformity, ileal kink, obstructing bands, long-standing hypertrophic stenosis, and enlarged mesenteric glands have in the past accounted for all our cases of gastric retention in children. We can now add to this list obstructing duodenal ulcer.

Reviews

EXPERIMENTAL PHARMACOLOGY

HEFFTER'S Handbook of Experimental Pharmacology was commenced more than twenty years ago, but owing to the war its publication did not start before 1919. The first two volumes were completed by 1924 and the first half of the third volume appeared in 1927. Since then there has been a long delay, doubtless due to the death of the original editor. The second portion of the third volume has now appeared¹ under the editorship of Professor HEUBNER, and the handbook is to be completed this year by a third and fourth portion of the third volume. As soon as the work is completed supplementary volumes will be produced in order to bring the earlier volumes up to date.

The part under review contains some 800 pages. Three-quarters of it is occupied by a monograph on iron written by Professor E. Starkenstein, and the remaining monographs deal with manganese, cobalt, and nickel, and the general pharmacology of metals. The handbook has somewhat altered its scope, for in the second volume, which appeared ten years ago, Professor Starkenstein dealt with the opium alkaloids in 300 pages, whereas in the present volume iron occupies 800 pages, and 100 pages are devoted to a metal of secondary importance, such as manganese. The article on iron is of an encyclopaedic nature, and gives a complete account of the history, chemistry, pharmacy, pharmacology, and metabolism of this metal. It includes tables giving the iron content of foods, mineral waters, and organs of the body, and others which show the original data of experiments on the action of iron in anaemia. Professor Starkenstein has himself made extensive investigations upon the intermediate metabolism of iron, and is therefore able to give a critical review of the experimental results. His monograph will be found of great value for reference by all who are interested in recent developments in iron therapy.

The promise of the early completion, with index, of Heffter's important work is very welcome, because there is no other handbook of pharmacology comparable in size and in scope.

IMMUNITY AND THE NERVOUS SYSTEM

It is not unreasonable to suppose that the nervous system may play an important part in resistance to infective diseases. The subject is specifically discussed in a book by Dr. METALNIKOV on the rôle of the nervous system in immunity.² The earlier chapters deal with observations on immunity in invertebrates, mainly directed to showing the preponderant influence of phagocytosis. The only antibodies detected in insects were bacteriolysins, although Chorine has demonstrated the development of a neutralizing substance analogous to antitoxin. The immunity developed in insects is, however, relatively non-specific; caterpillars immunized against cholera also acquired immunity to *B. paratyphosus* and *B. coli*.

The importance of the nervous system in the development of immunity is shown by ingenious experiments on caterpillars. If the third thoracic ganglion is destroyed immunity is not developed. If a tight ligature is tied round the middle of the caterpillar immunity is developed in the parts in front and behind the ligature, although only one part is immunized. If, however, the ventral nervous cord is burnt through, immunity is developed only in the part immunized. It must be noted

¹ *Handbuch der Experimentellen Pharmacologie*, Band III, 2 Teil. By A. Heffter and W. Heubner. Berlin: J. Springer, 1934. (Pp. 621-1502. RM.65.)

² *Rôle du Système Nerveux et des Facteurs Biologiques et Psychiques dans l'Immunité*. By S. Metalnikov. Paris: Masson et Cie. 1934. (Pp. 166; 25 figures. 28 fr.)

that, since the immunity is non-specific, it is not necessary to suppose that the nerves carry a stimulus specific for any particular organism.

The latter part of the book deals with the relation of conditioned reflexes to immunity. In the experiments described injections of foreign substances are accompanied by an external stimulus, such as sounding a trumpet or rubbing the ear. After several such injections the external stimulus is repeated without the injection and the presence or absence of a response observed. The most successful results were obtained with injections into the peritoneal cavities of guinea-pigs. In these cases the external stimulus, by itself produced a striking change in the number and proportions of cells in the peritoneal fluid. A not very striking rise of agglutinin titre in the serum (at most 100 per cent.) was produced in similar experiments. The author's judgement of what is significant in an experiment is weak. Thus (p. 134) he quotes a rise in the red blood count of 3,983,000 to 4,890,000 as evidence of concentration of the blood; and (p. 114) a 10 per cent. rise in the leucocyte count is considered significant.

TRAUMATIC SURGERY

The fifth volume of *The Practitioners' Library of Medicine and Surgery*³ covers the whole of traumatic surgery in its most liberal sense, even including articles on the surgery of the sympathetic nervous system and on post-traumatic states. In every instance the pathology, diagnosis, treatment, and prognosis are most fully discussed, and the value of alternative methods is considered. In the first chapter, for example, an article on burns includes no fewer than seven pages on the pathology, both clinical and experimental, of this injury. The systematic treatment of severe burns is dealt with in great detail, whilst all the modern methods of local treatment are examined with elaborate care and their value critically considered. Our sole criticism would be that the methods are perhaps too scientific, and could for the most part only be applied in a well-equipped hospital. We agree that severe burns ought to be treated under these conditions, but unfortunately such an ideal is by no means always attainable.

Fractures occupy one-third of the volume. Their pathology is illustrated by a series of masterly diagrams, the value of which is enhanced by appropriate x-ray photographs. The well-known treatises of Scudder and of Roberts and Kelly have been drawn upon extensively, and indeed the greater part of the illustrations appear to have come from these sources. The whole article is full of practical details of great value, and the minute description given of the treatment of fractures of the phalanges is only one example of the practical outlook of the authors. The short chapter on amputations is remarkable for the great beauty and clearness of its illustrations. We doubt, however, whether most surgeons would endorse the value placed upon a "Gritti-Stokes" amputation, even if they recognized its inverted name, while still fewer will have the optimism to indulge in "kineplastic" methods. Of great interest is the chapter on traumatic lesions of the thorax, for here at least modern methods have revolutionized our older conceptions. The complex pathology of pneumothorax is fully explained with its applications to the surgery of the chest. The surgery of the hand receives the full treatment demanded by such an important subject, and this should be of the utmost value to the house-surgeon. The traumatic surgery of the brain, of the spinal cord, and of the peripheral nerves are all treated with exceptional

fullness, and this section even includes an article on the traumatic neuroses.

The whole book is a masterpiece of production and of illustration, and the subject-matter is of equal excellence. While the scientific basis of treatment is given here in great detail, the approach is essentially practical, and on every page the reader will find those small details which make all the difference between success and failure.

TROPICAL TYPHUS

The confusion produced by the description of various forms of typhus fever in many parts of the world is such that it is a relief to turn to the unifying *Researches on Tropical Typhus* of Dr. LUDWIK ANIGSTEIN in Study No. 22 of the Institute for Medical Research, Federated Malay States.⁴ The author, after extensive experience of exanthematous typhus in Eastern Europe during the Great War and subsequently in Warsaw, spent two years in Malaya investigating the "tropical typhus" of Fletcher and Lessler, of which they found two types—the scrub typhus or K type, and the W (K19) or urban form, the infection of which was conveyed by mites or ticks. Dr. Anigstein has succeeded in conveying tropical typhus to guinea-pigs and rats, and in finding Rickettsia-like micro-organisms in the congested tunica vaginalis of these animals, and also in cultivating a pleomorphic organism and obtaining serological reactions with *B. proteus* X group, including both the K19 (W) and the K types, as well as from a large number of human tropical typhus cases. Moreover, after passage through guinea-pigs and rats, he produced the disease in a human volunteer by inoculating him with the brain of an infected animal.

No fewer than seventy-six strains of the organism were isolated from human and animal cases, and all forms, from Rickettsia-like ones, through bipolar-staining coccobacilli, and spindle-shaped organisms up to *proteus* forms, were obtained, and thus they closely resemble in every way those of typhus exanthematicus of Europe. Moreover, he took body lice out with him and fed them on tropical typhus patients; the results were fatal to the lice, with the development of enormous number of micro-organisms in them similar to those found in the tunica vaginalis of guinea-pigs and rats inoculated with emulsified infected lice and to those of European typhus. A vaccine made from cultures has also given promising results when used for prophylactic inoculation on a palm-oil estate highly infected by tropical typhus, for a rapid decline in the incidence of the disease followed, and only one case occurred subsequently among about 300 coolies receiving two doses. This memoir should be read by all interested in the widely distributed group of typhus fevers.

UROLOGY FOR THE PRACTITIONER

Hofrat Dr. FELIX SCHLAGINTWEIT in his *Urologie des praktischen Arztes*⁵ has produced a very useful and practical work, which has the merit of keeping absolutely to its title. It is truly a urology for medical practitioners, and deals entirely with the management of urological cases from the point of view of general practice. The author is careful to point out when a complete urological examination, or an operation, is indicated, and wisely

⁴ *Researches on Tropical Typhus: A Study of the Bacteriology, Serology and Epidemiology of the Disease.* By Ludwik Anigstein, M.D., Ph.D. Studies from the Institute for Medical Research, Federated Malay States. No. 22. Kuala Lumpur: Kyle, Palmer and Co., Ltd. 1933. (Pp. 186; illustrated.)

⁵ *Urologie des praktischen Arztes.* By Dr. Felix Schlagintweit. Zweite, erweiterte Auflage. Munich: J. F. Lehmanns Verlag. 1933. (Pp. 181; 104 figures. RM.7; geb. RM.8.20.)

³ *The Practitioners' Library of Medicine and Surgery.* Vol. v, *Traumatic Surgery.* By various authors. New York and London: D. Appleton-Century Company, Inc. 1934. (Pp. xlv + 1,080; illustrated. 50s.)

omits all details of specialized methods of treatment which are beyond the scope of the general practitioner.

The book opens with a very brief outline of the anatomy and physiology of the urinary apparatus. This is followed by an excellent description of case-taking and of the ordinary physical examination of the patient, the examination of the urine, and the indications for radiography and pyelography. The next section is devoted to the use and care of catheters and other urological instruments, the technique of passing them, and a description of the methods of irrigating the urethra and bladder. About two-thirds of the work is taken up with a description of urinary diseases, as seen by the general practitioner. The effects of obstruction are clearly indicated, and the dilatation of urethral strictures is excellently described. The section on prostatic hypertrophy is almost entirely occupied with the treatment of acute retention, the rules for self-catheterization, and the medical treatment of early cases.

In the chapter on urinary infections the author gives a short account of the haematogenous infections, which is followed by a more detailed account of inflammations of the different organs—urethra, prostate, bladder, kidneys, etc. About half the space is occupied with the treatment of gonorrhoea. In the chapter on stone the treatment of renal colic and of migratory calculi is well described. The indications for operation and the risks of calculous anuria are also clearly set forth. The chapter on tumours is mainly concerned with symptoms. The treatment of clot retention is carefully explained, and is the only complication which the practitioner is expected to treat.

After a chapter on injuries and malformations of the urinary tract, the book ends with one on diet in the treatment of urinary disease, which is exceedingly useful. All the descriptions are clear and concise. The teaching is sound, and the book is strongly to be recommended.

Notes on Books

Practical X-Ray Therapy,⁴ by Dr. HUGH DAVIES, is a small elementary textbook which will probably be of use to radiographers in preparing for the examination of the Society of Radiographers. The scope of the work is necessarily limited, but the information it contains is accurate and well arranged. Special chapters are devoted to apparatus, the measurement of x-ray dosage, and the general care of the patient whilst undergoing x-ray treatment. The remainder of the book deals, in a general way with diseases of the skin, diseases of the blood, of the nervous system, and so on. Suitable diagrams are used to illustrate the text, and an appendix contains diagrams giving the percentage depth dose under varying conditions. An adequate index completes this small volume, which can be recommended to those who wish to get some idea of the elementary facts connected with x-ray therapy.

La Cellulite,⁵ by Dr. L. ALQUIER, is a monograph in which an attempt is made to explain the majority of the reactions of the body in terms of changes in the cellular tissues. These changes, again, are related to constriction and dilatation of the blood vessels, and the associated reflexes are discussed. According to the author there exist, in addition to these changes in the blood vessels, corresponding changes in the connective tissues themselves, which he describes as "retractions," and his thesis is summed up in the statement that "to every irritation the organism responds by reactions of the vasomotor system and of the tissue retractility." These reactions become abnormal as soon as "adaptation to the modify-

ing causes ceases to be adequate." In the "neurostat" the author has discovered an electrical appliance which indicates these changes with precision, whilst he is able to stimulate and control these changes by means of irradiated metallic powders and certain homoeopathic substances in impermeable envelopes. The author is too modest to claim that his method will lead to the cure of cancer, but he assures us of his conviction that "the study and treatment of vasomotor perturbations and cellular retractions is the essential condition of the physical and moral equilibrium which are necessary for our happiness."

Secret Ways of the Mind,⁶ is a translation from the German of a book by Dr. KRANEFELDT of Berlin. The two opening chapters deal respectively with the early studies of double personality and the trauma hypothesis, but the main purpose of the writer is to provide the reader with an adequate sketch of the psychologies of Freud, Jung, and Adler. The author himself is an adherent of the Zürich school, and the book has the advantage of an introduction by Dr. C. J. Jung. The translation has been undertaken by Mr. RALPH M. EATON, who contributes a helpful preface. In this critical survey of the developments of dynamic psychology the fundamental differences between the conceptions of Freud and Jung as to the functions, origin, and content of the unconscious are admirably outlined.

An Introduction to the Biochemistry of Nitrogen Conservation,⁷ by Professor G. J. FOWLER, includes the substance of a course of lectures delivered by the author. It covers a wide field, for he starts with a general account of elementary bacteriology and biochemistry, and finishes with a full account of the technical details of sewage purification and the recovery and utilization of sewage nitrogen.

⁴ *Secret Ways of the Mind*. By Dr. W. M. Kranefeldt. Translated from the German by R. M. Eaton. London: Kegan Paul, Trench, Trubner and Co. Ltd. 1934. (Pp. 188. 6s. net.)
⁵ London: E. Arnold and Co. 1934. (Pp. 280; 6 plates. 12s. 6d. net.)

Preparations and Appliances

ANAESTHETIC MASK

Dr. A. D. Woolf (Highams Park, Essex) writes:

To overcome the disadvantage of an overflow of liquid from an anaesthetic mask on to the patient's face I have devised a mask with a deep gutter (seen in the accompanying illustration) which retains surplus fluid until it is reabsorbed by the gauze.

For those practitioners who of necessity have to rely upon the services of a nurse to give a little chloroform during a confinement the mask will be found very useful. It has been manufactured for me by the Medical Supply Association, 167-185, Gray's Inn Road, W.C.

⁴ *Practical X-Ray Therapy*. By Hugh Davies, M.A., M.R.C.S., D.M.R.P. London: J. and A. Churchill. 1934. (Pp. viii + 134; 47 figures. 8s. 6d.)

⁵ *La Cellulite, Primopathies, Vasomotrices, Retractions, Tumeurs*. By L. Alquier. Paris: Masson et Cie. 1933. (Pp. 228. 5frs.)

APPARATUS FOR SKIN GRAFT CUTTING

Mr. GRAHAM HUMBY (Guy's Hospital) writes:

For the successful cutting of skin grafts of large (superficial) area seven important requirements have to be considered: (1) the elimination of human error; (2) the production of a sufficiently large flat surface on the rounded contour of a limb; (3) the prevention of movement of the skin on the underlying tissues; (4) the avoidance of the considerable trauma involved in existing methods of fixing the skin; (5) the maintenance of uniform breadth and thickness

throughout the graft; (6) the provision of a readily sterilizable apparatus; (7) the maintenance of a sharp edge on the cutting blade.

I have evolved a machine, shown in the photograph, which has now been tried out in the operating room, and which appears to obviate all difficulties and meet the above requirements. It consists of a rigid rectangular framework, which is strapped on the limb. Tiny needles on a crossbar at either end pierce the skin to a depth of one-eighth of an inch, and allow of stretching of the skin surface, the degree of tension being adjustable by a simple ratchet mechanism. Sliding in the framework is a knife seven inches long and wafer-thin, which is removable and renewable in the same way as is a safety-razor blade. In front of this knife is a roller, which is so arranged that it precedes the cutting edge by one-eighth of an inch, and thus constantly presents to the knife as it advances a flat skin surface from which to cut. The angle at which the cutting edge meets the skin is adjustable, and allowance is made for a to-and-fro movement through a range of one inch in a direction at right angles to the side members of the frame. This allows the knife to be used after the manner of a saw, advancing little by little with each thrust.

Grafts of different thicknesses can be cut with the same instrument by varying the depth of the cutting edge, and simple adjustment regulates their breadth up to the maximum available on the limb. Human skill is almost completely eliminated, and so the need for practice is reduced to a minimum. The machine should prove of particular value to the general surgeon who is called upon to perform a skin-grafting operation on only rare occasions, enabling him to cut large grafts with comparative ease. It is made by Down Bros.

HUMIDIFYING APPARATUS FOR INFLATION OF TYMPANUM

Dr. R. YOUNG KENNY (London, W.) writes:

Since inflation of the tympanum is so frequently used in otological practice, this simple modification of the apparatus may be of interest to aural surgeons.

The apparatus consists of: (1) a vacuum flask with a 3-in. cork stopper (capacity a little over an imperial pint); (2) one thistle funnel with stem passed through the cork and reaching to within an inch of the bottom of the bottle; (3) a bent tube which passes just through the cork, and is connected to (4) the tube to the inflating bag. The latter has two valves, arranged so that air is drawn from the flask and forced through the connecting tube to the end of the Eustachian

catheter, or, in the case of Politzerization, to the nasal tip. The object of the apparatus is to supply for inflation air which has been warmed, humidified, and cleaned. This is doing what the normally functioning nose does to the inspired air which normally ventilates the tympanum. The ciliated epithelium which lines the Eustachian tube and the tympanum is affected by cooling, by drying, and by dust- and germ-laden air, as well as by the irritating gases with which our atmosphere, especially in crowded city areas, is laden. The old method of inflation, whether done by the use of the compressed-air tank, the electric pump, or the Politzer bag, does not take these defects into account.

The vacuum flask is first rinsed with hot water (boiling), and then half filled with boiling water and corked. The thistle funnel should previously have had its mouth loosely stuffed with sterile absorbent cotton-wool, and covered with a double thickness of gauze held on by an elastic band. Now about six or eight squeezes of the bag will draw off the air left in the bottle, and replace it with filtered air entering by the thistle funnel and going through the water. The tubing and bag will also be warmed. The bag is like the 10-oz. Politzer bag, with valves at each side allowing the current of air to go only in the one direction—from vacuum flask to patient. If it is desired to introduce some volatile medication this may previously be added to the water.

At first a thermometer was used, passed through the cork to give the temperature of the air in the upper half of the flask, but this was found unnecessary, because, though the air comes warm after about eight squeezes of the bag, it never comes too hot. This can be tested by placing a catheter inside one's cheek and pressing the bag many more times than is ever used in an inflation treatment.

Before each inflation squeeze the bulb two or three times to expel any condensed moisture which may collect in the tubing. The Holburn Surgical Instrument Company made the bag, with connecting tubes and valves, for me.

A SPIRIT-CONTAINING INSTRUMENT CASE

Allen and Hanburys Ltd. have recently brought out the instrument case shown in the accompanying figure. It consists of a nickel-plated cylindrical metal case 6 in. high by 3½ in. in diameter. In it is fitted a removable rack or stand carrying a number of instruments required for minor surgical operations. The case is filled with spirit so that the instruments are quickly available in a sterilized condition. A screw-on cover with cone fitting is provided, which prevents leakage of spirit. In use the rack is lifted out and placed on the inverted case cover.

The following equipment is provided: two 5-in. Spencer Wells forceps, one 5-in. dressing forceps, one 5-in. scissors (blunt-pointed), one 5-in. sinus forceps, six suture needles in metal container, one "A. & H." knife-handle, six "A. & H." knife-blades in metal container, one director and scoop, one trocar and cannula, one 5-in. silver probe.

The case weighs about 2 lb. 12 oz., and prices range from £1 12s. (case with lift-out rack to carry own instruments) to £4 12s. (case complete with stainless steel instruments). With nickel-plated instruments it costs £3 15s.

DENTAL SURGEON

AND

G. E. FRIEND, M.R.C.S., L.R.C.P.
MEDICAL OFFICER

CHRIST'S HOSPITAL, HORSHAM

An account of a public school dental clinic carried on under uniform conditions during the eleven years from 1923 to 1933 inclusive may be of practical interest. The school in question, Christ's Hospital, Horsham, has an average boy population of over 800, the yearly turnover being about 150. The boys are under regular dental supervision, the dental surgeon attending one day a week during term time, and where after-care is necessary it is carried out by the resident medical officer. The figures obtained in the dental record are of interest, and we are prompted to show the further improvement possible in a school which in 1923 was already comparatively clean-mouthed.

In 1923 attention was centred, as previously, on the discovery and rectification of caries, and on the irregularity of teeth, etc. In September, 1923, dental certificates were required for new boys entering the school, and in November of the same year a "clean mouth campaign" was instituted. It was considered that the best way further to improve the oral condition of the boys was to institute a standard for cleanliness. Clean gums and teeth are conducive to the prevention of pyorrhoæa alveolaris and caries, and to the improvement of health through the reduction of those minor ailments and diseases which are conveyed by droplet infection.

The work at Christ's Hospital comprises: (1) charting cavities; (2) notifying parents of irregularity of teeth; (3) carrying out any urgent extractions; (4) doing urgent temporary or permanent fillings; (5) adjusting regulation appliances; and (6) dealing with accidents—for example, fractured, loosened, or evulsed teeth, or fractured jaws. Routine examination is made on every boy, when the mouth is graded. Each house (about fifty boys) is examined as a whole, and any caries or irregularity of the teeth is notified to the parent for attention next holidays, only urgent repair work or extraction being done at school. Every boy whose mouth requires attention is seen at the beginning of the next term, to make sure that the work has been carried out; in those cases where this has not been, or is improperly, done, a second report (or in occasional stubborn cases a personal letter) is sent, and followed up until the work is completed. This system of examination appears to us, after ten years' experience, to be sufficient to ensure a healthy condition of the mouths throughout the school. Occasions for controversy arise principally from the neglect of parents to take boys to a dentist. Disputes do not arise between the home dentist and ourselves.

Since January, 1926, the boys have been graded into four divisions of oral cleanliness: A1, 1, 2, 3. A1 and 1 indicate clean mouths, the view being taken that it is more of an incentive to the boys to be classified as A1 and 1 for clean mouths than as 1 and 2. A1 is a super-clean mouth, and 1 is a clean mouth with, say, fillings or loosening deciduous teeth, making a distinguishing difference. The other two divisions, 2 and 3, indicate dirty and very dirty mouths. The boys in these divisions have to be rendered A1 or 1 with hard brush drill and scaling and cleaning, and have to attend regular inspections until the teeth are clean enough for the boy's promotion. In cases of stomatitis suitable mouth-washes are prescribed, and remedial treatment is given. Tonsils and adenoids and other possible causes of oral sepsis also receive attention.

This yearly classification has been carried out in the same manner since 1926, and the progress which has been made is shown in the following table:

TABLE I.—Grading of Mouths (Excluding New Boys)

Grade	1926	1927	1928	1929	1930	1931	1932	1933
A1	453	525	550	545	580	573	603	572
1	301	240	234	223	199	155	178	206
2	40	22	22	18	13	12	19	14
3	11	4	—	—	—	—	—	—
Total examined	815	792	806	792	792	771	800	792
Percentage								
A1	56.8	66.4	63.2	69.0	73.2	74.1	75.4	72.2
1	37.0	30.3	29.0	28.7	25.1	24.0	22.2	26.0
2	4.9	2.8	2.7	2.2	1.6	1.5	2.3	1.7
3	1.3	0.5	—	—	—	—	—	—
A1 plus 1	93.8	95.7	92.2	97.7	98.3	98.4	97.6	98.2
2 plus 3	6.2	3.3	2.7	2.2	1.6	1.5	2.3	1.7

This campaign for "clean mouths" has been easily conducted at Christ's Hospital. Occasionally masters have been appealed to when the whole house has been backward, but for the individual case the house captain has always carried out instructions, and has seen that the gums and teeth of those boys who were dilatory in scrubbing them were in a better condition when next inspected. In fact, the label of a 2 or 3 is considered a stigma by the boys.

A point of great value is to investigate and explain the reason for a lapse from a clean mouth to one of poorer grade. The usual cause is either laziness, coupled with a weak arm and a soft toothbrush, or a lapse in general health—for example, by the development of chronic sepsis in tonsils and adenoids. From Table I it will be seen that Class 3 mouths are now non-existent, and that the number in Class 2 is vastly reduced. Also there is a general elevation from Class 1 to the peerage of A1. Coupled with this increase in the number of clean mouths there has been about a 20 per cent. reduction in the number of cavities, and a 14 per cent. reduction in the number of boys with carious teeth.

After ten years' work on these lines we are of the opinion that an average figure of 1.5 cavities per boy is the irreducible minimum of caries, and 2 per cent. that of mouths below Grade 1. When such a clean mouth campaign is carried out systematically there is the tremendous prospect that teeth will be retained longer than at present, and that pyorrhoæa alveolaris and such conditions will be deferred, if not altogether avoided, with the result that this improved condition must repercuss upon the general health of the individual and the community.

TABLE II.—Caries (Including New Boys)

Year	Number of Boys without Caries	Number of Boys with Caries	Percentage of Boys with Caries	Cavities per Boy
1923	355	432	54.8	1.96
1924	411	379	47.5	1.82
1925	556	357	39.1	1.69
1926	479	424	45.9	1.68
1927	534	356	43.6	1.69
1928	505	386	43.3	1.60
1929	523	341	42.1	1.69
1930	438	373	43.7	1.75
1931	563	331	37.0	1.45
1932	473	324	43.3	1.54
1933	523	322	35.4	1.57

SELENIDE TREATMENT OF CANCER

A CRITICAL REVIEW

In a recent paper¹ Dr. A. T. Todd gives an account of the modifications introduced into the method of colloid treatment of cancer, begun in Bristol eight years ago, with colloidal lead selenide. The changes are, briefly, the elimination of lead entirely, except for the local application to ulcerated growths of lead amalgam ointment, and the substitution of two new colloids—a sulphur selenium colloid "SSe," and a radio-active selenium colloid "R.A.S." In the latter, selenium is combined with feebly radio-active radium residues, radium G and higher disintegration products.

The treatment begins with intravenous injection of SSe, followed two days later by $1\frac{1}{2}$ Holzknecht units of deep x rays. The reaction which follows each of these procedures—mild exacerbations of symptoms—is carefully noted, and the repetition of both at weekly intervals aims at maintaining this degree of reaction, the dose of colloid and of x rays being adjusted accordingly. This first course lasts eight weeks—that is, till 12 H of x rays have been applied. Alternation then begins, and for three weeks a weekly dose of R.A.S. is administered, again aiming at a moderate but definite reaction. SSe and R.A.S. are then given on alternate weeks for a period of six months. In a case progressing satisfactorily injections then cease for eight to ten weeks, after which a further course of alternating SSe and R.A.S. is maintained for three months more. When progress has continued for nine months treatment is stopped, and the patient attends for observation only for a further period of six months. He is then discharged, being warned to return if any suspicious symptoms occur.

Theoretical Conceptions

It will be obvious from this summary that even in favourable cases treatment is tedious; in unfavourable cases it may last longer, and is continued till the patient is moribund, for even in desperate cases improvement may ultimately set in. In discussing the reasons for the modifications embodied in his new methods Dr. Todd draws attention to the exacerbation of the disease which followed the attempt to combine x - or radium-radiation in therapeutic doses with the earlier colloidal lead selenide (D4S) treatment. Excessive doses of the colloid gave the same result in animal experiments. This effect Dr. Todd believes to be due to the presence of the radiation-sensitive selenium, converting a relatively small into a relatively large dose of radiation, as it is well known that excessive radiation of an insensitive new growth may lead to aggravation of symptoms and more rapid progress. It is possible, as he maintains, that these effects are in both cases due to damage of a defensive mechanism.

In an interesting digression Dr. Todd expounds his conviction that the new growths are the result of an infective virus, and that his treatment is successful because it is adapted to this conception of the disease. The reviewer does not believe that this is necessarily true. Even in the filterable tumours of the fowl, in which the evidence for the participation of a causative virus is strongest, the virus is so firmly combined with the cell structures that even the strongest viricidal antisera (active against filtrates) are incapable of rupturing the combination and of robbing living cell-suspensions of their property of giving rise to new growths. Still less is this possible in a growing tumour, and for pathological and therapeutic purposes the cell, with its contained infecting agent, forms an indissoluble pathogenic entity. If an analogous cell-

virus complex subsists in the neoplasms of mammals the unification is even more complete, and the therapeutic problem is essentially the problem of the destruction or encapsulation of the parenchyma cells of the new growth. This encapsulation is essentially a non-specific overgrowth of the stroma, and it may be brought about in a variety of ways. It is still impossible to predict the outcome of treatment by these procedures because rather narrow limits are set to the amount of stimulation the stroma or "junction tissue" can tolerate, and because of the second incalculable variable—the inherent malignancy or virulence. This varies from one neoplasm to another, but is relatively constant in any one tumour. The upper threshold of effective stimulation of the "junction tissue" cannot be passed without disaster. Hence it comes about that only by the therapeutic test can the cancer cases be distributed into the classes in which the treatment is more or less successful or fails.

Results of Treatment

After discussing the prognosis, both from the purely clinical side and from the outcome of certain laboratory tests, Dr. Todd gives the results of the treatment of two series of cases. Series I, May, 1931, to September, 1932, comprises ninety-five unselected cases, untreatable by surgeon and radiologist. In this series, of those patients who had completed an adequate course twenty-nine have died and fifteen are alive and well. Three patients apparently cured died from other causes. In series II, sixty-two cases, unselected as to clinical and pathological state, twelve patients who had received adequate treatment have died and three have been discharged as apparently cured. In assessing the significance of the duration of freedom from symptoms it should be remembered that the apparently cured have been under observation for six months without treatment before discharge. From the data supplied it is not possible to ascertain the survival times after "toilet" operation, and many will regret this omission. Dr. Todd informs me this interval has never been less than six months before discharge: usually "toilet" operation, or, for example, colostomy, is done at the beginning of the treatment.

Summary

To sum up, approximately 20 per cent. of unselected patients with cancer, rejected by surgeon and radiologist, have been restored to health. Of the remainder a considerable fraction have shown temporary improvement. Is this method of combined colloid and radiation therapy which Dr. Todd has developed with a patience, ingenuity, and sustained enthusiasm that all must recognize, capable of still further improvement? Or does it effect an unconscious, unforeseeable selection of a group of patients who, left untreated, would die, but having the germs of a defensive mechanism and a not too high degree of malignancy of their neoplasms, can have the scale turned in their favour? Only by a wider test of the method by others, and by its application as a preventive of recurrence after operation as Dr. Todd suggests, can this fundamental dubiety be satisfactorily resolved.

J. A. MURRAY.

The twenty-second annual report, in the *Journal of the American Medical Association* of May 19th, on the ninety-three cities of the United States with a population of more than 100,000 shows that for the first time since the summaries were undertaken no city registered a typhoid mortality rate higher than 10 per 100,000. Sixteen cities had no typhoid deaths at all—an unprecedented record. The improvement is probably somewhat greater than the figures indicate, since the estimate of the 1932 population is made without allowing for possible increase.

SATURDAY, JUNE 16th, 1934

DIPHTHERIA IMMUNIZATION

Diphtheria, an almost preventable disease, still attacks some 40,000 people every year in England and kills 2,000; it naturally attracts, and will continue to demand, much attention from medical writers and workers. W. T. Benson,¹ in an impressive review of the position in Britain, again points out that in a crucial test in the Edinburgh and Birmingham isolation hospitals immunization virtually abolished diphtheria among the staff and the nurses constantly and intensely exposed to risk, and that the analysis of the large American figures by Godfrey² and Lee³ reveals a like happy sequence. In Benson's view we have been merely toying with diphtheria prophylaxis in Great Britain. Prophylaxis will save money; even a moderate appeal to parents influenced 80 per cent. of them to give consent to immunization. He urges the free provision of toxoid by the local authority and a payment to the general practitioner who injects the prophylactic, the initial Schick test and retest being omitted among young children. Two campaigns embracing the general practitioner are announced from West Kensington and Lincoln.⁴ Benson warns against making one's promises to the public too comprehensive, for there will always be a small residue of children not immunized, "and 'notifiable' diphtheria will occur even in immune individuals so long as every sore throat, from which a few morphological Klebs-Loeffler bacilli have been cultured, continues to be erroneously regarded as necessarily diphtheritic."

We referred in our issue of February 17th (p. 290) to the remarkably successful use of toxoid in Canada. G. Ramon,⁵ in a recent summary, describes immunization with formol toxoid ("anatoxine"). Working with more potent toxoid—containing 20 immunizing units per c.cm.—than previously, he has obtained excellent immunity with three or even two injections containing 3 c.cm. of toxoid. R. A. O'Brien and H. J. Parish,⁶ who employed toxoid of even higher value, with the effective avoidance of reaction provided by the useful Moloney-Fraser test, converted 95 per cent. of children from Schick-positive to completely negative within a few weeks. Swyer,⁷ with formol toxoid, obtained 93 to 100 per cent. change to the Schick-negative state within four to twelve weeks after two or three injections. The toxoid made by C. G. Pope and M. Healey⁸ of the strikingly high value of ninety-two antigenic units presumably is also being used for immunization. Formol toxoid may be regarded as

almost a tried friend. It must, however, be given in at least two spaced doses. The possibility of obtaining reasonable immunity with but one dose has attracted much attention recently. Great hope is centred on "localizing" the toxoid injected; this can be done with alum (Glenny) or with tapioca or typhoid vaccine (Ramon). The action of alum is remarkable. In 1925 A. T. Glenny, C. G. Pope, H. Waddington, and U. Wallace⁹ discovered that the addition of alum provides a precipitate of high immunizing power even in one dose. This alum toxoid precipitate has been continuously tried during the past few years in England and is still being cautiously used. W. H. Park, with handsome acknowledgement of the English work on which the method was based, reported in 1930 at the International Congress in Paris highly successful results with this form of alum toxoid, but states that the reactions with alum toxoid are annoying though not in the least harmful. The employment of alum toxoid has been enthusiastically adopted in some of the Western and Southern States in the U.S.A., with gratifyingly high conversion of Schick-positive children to negative after one dose. It is of interest that the induration or "lump" which occurs in a few patients, and the rare abscess, have been tolerated by American parents, who are presumably more amenable than our own public. Saunders¹⁰ recently made an inquiry in Ireland into the tendency of different batches of precipitated alum toxoid to cause induration and abscess. In the U.S.A. W. H. Park¹¹—the honoured pioneer in this field—working with J. D. Munro and V. K. Volk, after a carefully controlled investigation, has just recorded with wise moderation that toxoid with the addition of 0.2 per cent. alum, in two doses, gave an 89 per cent. Schick-negative result at the end of two months and 94 per cent. at the end of a year. McGinnes and Stebbins,¹² in Virginia, describe the injection of one dose of precipitated alum toxoid into small groups of children with a resulting conversion from positive reaction to negative in 94 to 96 per cent. The biochemist may be trusted to provide purer alum toxoid in the near future, and so virtually abolish the unwelcome "lump" that still hinders the general introduction of this method of immunization.

So much for the severely practical aspects of immunization: those who would look further will enjoy the lengthy and philosophic report by S. F. Dudley, D. M. May, and J. A. O'Flynn,¹³ the latest contribution by the Medical Research Council to a task so competently started in 1923 with the classic, *Diphtheria*. These authors state that amongst a changing population of boys at Greenwich Hospital School—approximately 1,000 at any moment—there were from 1919 to 1927 385 cases of "diphtheria," while in five years following active immunization, then tardily authorized, forty-four infections labelled "diphtheria" were recorded, of

which only eight were clinically recognizable; of these, six occurred in Schick-positive boys before inoculation. The authors have garnered a rich harvest of observations and conclusions. Active immunization gives almost certain protection against recognizable clinical diphtheria: gravis bacilli infected the school in 1932; mitis predominated in 1933; one boy in four had virulent K.L.B. in his throat during 1932; gravis bacilli are more invasive than mitis, since they may cause, in Schick-negative people, a trivial illness called "diphtheria," but active immunization is a sound method of protection against recognizable clinical infection with gravis bacilli. A virulent carrier state may exist with a Schick-positive reaction. Tonsillectomy has no effect on Schick immunity. Ten per cent. of boys artificially made Schick-negative may become Schick-positive in from six months to four years, but this loss is of little practical consequence, for, in the event of infection, the clinical result is usually trivial. The figure given contrasts with those of H. J. Parish and C. C. Okell,¹⁴ who ascertained that only 2 to 5 per cent. of children in a school had lost the full Schick-negative level when tested two to several years after immunization; Nélis,¹⁵ in a recent report, confirms these findings. Even where the conclusions of Dudley and co-workers are heterodox, criticism is blunted by the authors' own disarming self-criticism. Thus, after arguing ably for some pages that artificial immunization may increase the "virulent carrier rate" and the occurrence of diphtheria among the inoculated—a conclusion probably unacceptable to Godfrey and Lee, who have analysed the large American figures—they admit that in Hamilton, Canada, the opposite conclusion was reached; a special "caution" also warns the unwary against necessarily regarding the observations and conclusions as applicable to other populations or even to the same population at different times. A survey of all this recent activity convinces one that the fever specialist, the immunologist, and the health officer are alert to remedy the present unsatisfactory position. What of the responsibility of the parent and general practitioner, and of those who oppose preventive inoculation?

THE CONTROL OF THE DIGESTIVE FUNCTIONS

Recent investigations have extended our ideas about the control of the digestive functions in certain rather interesting directions. The older views may be divided into the following three mechanisms: psycho-neural reflexes, neural, and humoral. The psycho-neural, or conditioned, reflexes were most clearly demonstrated by the work of Pavlov and his pupils, and need no further reference here than to point out that the claims made as to their philosophical significance are not as readily substantiated. There can be no doubt that these experiments show that in some subtle way the brain can transform psychological receptions into

nerve stimuli, but this does not provide sufficient grounds for concluding that what we call "mind" is entirely a complex system of such transformations, or for explaining all mental phenomena on a purely mechanistic basis. The link between the psychological receptor and the nerve stimulus is entirely unknown to us, and we cannot picture precisely what takes place when a hungry dog as a result of the sight or odour of food begins to salivate or secrete gastric juice. Nor is it easy to understand how a secretion of gastric juice can be initiated by the suggestion of certain food to a patient under hypnosis. What picture can be drawn of the train of events which leads to an attack of vomiting on the receipt of bad news? What is the basal element leading to the frequently severe gastro-intestinal dysfunction associated with hysterical dissociation? We have as yet to be content with the term "psycho-neural," and must await greater understanding of mind processes before these phenomena are likely to become understandable in more physiological terms.

The control of the digestive functions on a lower plane by the relatively simple neural mechanisms falls more or less into line with our general conceptions of vegetative reflexes. Humoral control of the digestive system is now a well-established fact. Although doubt still exists in the minds of many physiologists as to whether the gastrin hypothesis is tenable in its original form, recent work has shown that histamine, or histamine-like substances, can be obtained from the gastric mucosa, and these may lead to the consequences formerly attributed to the hypothetical gastrin. In a recent contribution Okada¹ draws attention to a substance extractable from spinach, which he calls "spinacin," and which has a powerful stimulant action on the gastric and pancreatic secretions when injected subcutaneously: given by mouth it is inactive. Spinacin appears to be an imidazol derivative, and is readily distinguishable from histamine. The stimulant action of spinacin on gastric and pancreatic secretions is unaffected by section of the vagi or by injection of atropine, so that it seems to be a member of the group of humoral agents acting on the digestive glands. Like histamine it does not produce its effects on these glands when injected in relatively large doses into the circulation, apparently because of toxic action on the secreting cells; but when introduced subcutaneously, intramuscularly, or very slowly intravenously, a striking response is obtained.

Okada has also used this substance in the treatment of achylia gastrica, hypochlorhydria, and in gastric cancer. In all of these cases a few days' treatment with the spinach extract so far changed the reactivity of the gastric glands that, whereas both test meals and histamine had previously evoked little or no response in the matter of acid, they now gave normal or almost normal curves of free and combined acidity. In the same work Okada presents a considerable mass of evidence in support of another mechanism of gastro-

¹ *Nagoya Journ. Med. Sci.*, December 20th, 1933.

intestinal control—namely, a humo-neural mechanism. This conception found its earliest support in the observations of a good many workers on the action of insulin. While the immediately recognizable result of insulin injection is a fall in blood sugar, a whole series of phenomena were gradually described as occurring when the blood sugar fell to hypoglycaemic levels. Outstanding among these phenomena was hunger, and it was soon demonstrated that hypoglycaemia leads to increased gastric motility and increased volume and acidity of the gastric juice. The peculiar thing about these results of hypoglycaemia was that they could be prevented by section of the vagi or by the injection of atropine, as well as by glucose. These results lead to the view that hypoglycaemia stimulates the vagal centre and so gives rise to the motor and secretory sequels observed. Now whereas this humo-neural mechanism is brought into action by a fall in blood sugar, a similar end-result is obtained by the injection of various amino-acids, with consequent increase in blood amino-acids. The effect of the latter on the vagal centre can be demonstrated in the same way as in the case of hypoglycaemia, and can also be prevented by the injection of glucose. Exactly similar responses were demonstrated by Okada for the pancreatic and the biliary secretions, but not for the succus entericus. For the pancreatic juice the humo-neural mechanism is best brought into play by fat, which leads to the secretion of a juice rich in ferment and thus simulates that obtained by vagal stimulation. This action of fat can be prevented by hyperglycaemia, section of the vagi, or by atropine. These and other experiments described by Okada deserve repetition and critical study.

THE DENTAL BOARD AS FAIRY GODMOTHER

The third Dental Board since the passing of the Act of 1921 has held its final session, and its chairman, Sir Francis Dyke Acland, took occasion to give a short summary of what has been accomplished in the way of dental education, research, and health propaganda. The Board, in one of its functions, is a stern disciplinarian, but in another it is a fairy godmother, showering gifts on the deserving. Out of its total income over the twelve years of a little over half a million it has allocated as grants to students a sum of £173,000; it has given £53,000 to dental schools for extension and equipment; and it has voted £52,000 for research and £34,000 for dental health education. In addition, grants in aid of teaching in dental schools have been given to the amount of £10,000, and a like sum has been expended on post-graduate and post-registration lectures. The grants to the dental schools have enabled three of them—Glasgow, Leeds, and Newcastle—to provide new buildings and equipment, and six others have been helped to make structural alterations. In this same session, but after the chairman had spoken, a grant of £5,000 was offered on the usual conditions to the University of Birmingham towards the cost of its proposed new dental school at Edgbaston. The grants in aid of teaching in dental schools have been made on the basis of a definite
